Nevertheless, this complication could easily be dealt with. In calculating the economy-wide amount of profit inclusive of interest, and the average rate of such profit, interest payments to financial institutions could be excluded. They could be treated as part of productive expenditure, as part of the business sales revenues constituted by productive expenditure, and as part of the costs deducted from the sales revenues of the firms that make the payments. This procedure would serve to reduce the sum of profit and interest income in the economic system by the magnitude of the interest payments made by business firms to financial institutions, and then

to increase it by the magnitude of the profits earned by such institutions on those interest payments and by the amount of interest income those institutions paid to individuals. The net effect would be to reduce the sum of profit and interest income in the economic system by the magnitude of the costs incurred by the various financial institutions, apart from their payment of interest to individuals. The procedure would thus turn out to be tantamount to the assumption both that all interest and dividend payments were made to individuals, which, of course, is the assumption on which I am proceeding, and that their amount is net of the costs incurred by financial institutions, apart from the latter's payment of interest to individuals. It should be observed that the procedure would serve to convert part of what would otherwise be interest incomes that had to be added to profits, into literal profit incomes—namely, the profit incomes earned by financial institutions on interest revenues. However, to avoid even this much complication, I will, as I have said, simply ignore the existence of financial intermediation.

The Rate of Profit Not Based on Demand and Supply of Capital, but on the Difference Between the Demand for Products and the Demand for Factors of Production

My treatment of interest is consistent with a simplified view of productive expenditure as consisting exclusively of the demand for capital goods and producers' labor (that is, of course, labor employed by business). This makes it possible to speak interchangeably of productive expenditure and the demand for factors of production by business. The two expressions become equivalent.

If, in contrast, the payment of interest were retained as part of productive expenditure, then using the two expressions interchangeably would imply that the payment of interest was a demand for a factor of production in the same way that the demand for capital goods and producers' labor are demands for factors of production. The further implication would be that capital was a factor of production standing alongside of and in addition to capital goods and producers' labor, inasmuch as capital is what is obtained by the payment of interest.

Such a view represents a confusion of ideas. Capital in the sense of a sum of money used to make productive expenditures and thus buy factors of production, or in the sense of the monetary value of the factors of production purchased, is not itself a factor of production. It is simply the means of buying the factors of production, or it is their recorded acquisition value on the books of the firms that buy them. The actual factors of production are capital goods and producers' labor, not capital goods, producers' labor, and capital.

These considerations are extremely germane to the

question of what determines the average rate of profit in the economic system. As we shall see, in no sense is the rate of profit determined by the supply of and demand for "capital." Rather, it has everything to do with the difference between two demands: the demand for factors of production by business—that is, the demand for capital goods and producers' labor—which shows up as costs of production to be deducted from sales revenues, and the greater demand for the products of business, which constitutes business sales revenues. Profit, in essence, is the difference between these two demands. Explanation of the rate of profit and interest must be geared toward explaining the difference between these two demands, not a demand for and supply of "capital," in which capital is mistakenly conceived as a factor of production.⁶

Determinants of the Average Rate of Profit in the Economic System Different from Determinants of the Rate of Profit of the Individual Company or Industry

Although by now it should go without saying, I cannot stress too strongly that what I intend to show in this chapter is the determinants of the average rate of profit in the economic system of a country, indeed, of the world. As I have already indicated, the determinants of this rate of profit are very different from those which determine the rate of profit of an individual company or industry. At the level of the individual company or industry, competitive factors play a major, often by far the largest, role.⁷

For example, an individual company that introduces a new and improved product is in a position to increase its profits substantially. It does so, however, by gaining sales revenues at the expense of other companies with which it directly or indirectly competes, and which now experience either an outright reduction in sales revenues or else a failure to gain sales revenues that they otherwise would have gained. As illustration, this was the case with the automobile, which competed not only against the horse and buggy and the railroads but also against industries outside the field of transportation. In the absence of the appearance of the automobile, many of these industries would have gained additional sales revenues as the result of the release of funds from the purchase of such things as food and clothing, made possible by greater efficiency in the production of such goods. Instead, the automobile industry garnered much of these funds. The same is true in all instances in which increases in profits are based on competitive factors. The accompaniment of all such increases in profits is, of course, corresponding decreases in profits elsewhere.

These observations are consistent with what I have said previously about the fact that technological progress

does not raise the average rate of profit. It raises the rate of profit of those firms that introduce the technological advances or are relatively early in their adoption, and equivalently reduces the rate of profit of other firms, in the rest of the economic system. As I have shown, the only way in which technological progress can raise the average rate of profit in the economic system is insofar as it takes place in the production of the monetary commodity or commodities, namely, in the production of gold and silver under a precious-metals monetary standard, and thereby achieves a more rapid rate of increase in the quantity of money and volume of spending.⁸

Whole industries, as well as individual companies, are in a position to make higher profits or lower profits, or profits versus outright losses, on the basis of competitive factors. This occurs every time the consumers shift their demand from the products of an industry that has lost their favor to the products of an industry that has gained their favor.

The determinants of the average rate of profit in the economic system, in contrast, exclude all competitive factors. In the economy as a whole, competitive factors are always mutually offsetting. They cannot explain why or to what extent the sum of profits of the individual firms that have profits exceeds the sum of the losses of the individual firms that have losses, that is, why and to what extent there is an aggregate profit in the economic system and thus a positive average rate of profit, nor the specific height of the average rate of profit. To answer these questions, it is necessary to turn to an examination of factors that are very different than the competitive elements that are so vital to the determination of the rate of profit of individual companies and industries.

That the explanation of an aggregate profit and thus a positive average rate of profit depends on different factors than the competitive elements that loom so large in the case of individual firms and industries means that it should not be surprising if a very different significance is often to be attached to the existence of a given average rate of profit in the economic system than to the existence of an equal rate of profit on the part of an individual company or industry. It is one thing if outstanding productive innovators earn, say, a 50 percent annual rate of profit. Such a situation is consistent with the average rate of profit in the economic system being perhaps just 5 percent, and with other businessmen, who are backward and incompetent, suffering reduced profits, including outright losses, that are as large as the exceptional profits of the great innovators. Here the high profits of the innovators are due almost entirely to the improvements in production they introduce or are early to adopt. It is a very different situation if the average rate of profit in the economic system is 50 percent, with the result that even

the most backward and incompetent businessmen can earn a substantial rate of profit. In the latter situation, as we shall see, what is present is rapid inflation of the money supply and/or a state of affairs in which the great majority of businessmen and capitalists have come to value a much higher degree of present enjoyment relative to provision for the future. This situation signifies economic decline and impoverishment, while, as we well know, the former situation, in contrast, signifies economic progress and prosperity.

Critique of the Doctrine That the Interest Rate on Government Bonds Expresses the Pure Rate of Return to Which Risk Premiums Are Added

My focus on the determinants of the average rate of profit on capital invested is incompatible with the notion that the rate of interest on government bonds expresses the pure rate of return on capital, and that higher rates of return represent an addition of various premiums to this alleged pure rate, which compensate for risk or uncertainty.

I showed in Chapter 6 that it is possible, indeed, likely, that the rate of profit in the narrower sense, that is, the rate of profit on equity investments, is above the average rate of profit, while the rate of interest is below the average rate of profit.⁹ It follows that the rate of interest on government bonds, being generally the lowest in any country, will be correspondingly further *below* the average rate of profit, and not in any sense represent a "pure" rate of profit.

Furthermore, insofar as a "risk" premium merely serves to offset losses on other investments of the same kind, it does not enter into the average rate of return that is actually earned. For, presumably, the losses for the provision of which the risk premium exists do in fact occur, in which case the average rate of return being earned is below the nominal rate containing the risk premium. A risk premium which is merely an offset to losses cannot constitute an element in any average rate of return which is actually earned or paid.

It is different with regard to uncertainty, however. Because of uncertainty, there may be permanent differences in rates of return actually earned. But these rates do not ascend upward from the lowest rate, which allegedly represents the "pure" rate, each containing a premium in addition to the "pure" rate of return. Uncertainty in investment is inescapable, and relative uncertainty cannot add anything to the average rate profit. All that can occur is that those investments of a relatively high degree of uncertainty will afford a rate of profit in excess of the average rate of profit, while those investments of a relatively low degree of uncertainty will afford a rate of profit below the average rate of profit.

The Path of Explanation: Net Consumption and Net Investment

In its explanation of profits, this chapter follows a path that was indicated in Chapters 13 and 14. There, under the assumption of the complete vertical integration of business and thus that business firms produce all of their own materials and equipment and buy nothing but labor services, I showed that consumption expenditure would constitute the only source of business sales revenues and that wages would constitute the only costs incurred by business. It followed that aggregate profits would equal consumption minus wages, which excess I termed *net consumption*.¹⁰ In this chapter, I show that net consumption is *always* the most fundamental determinant of aggregate profit and the average rate of profit, irrespective of the extent of vertical integration of business firms. I then trace the phenomenon of net consumption back to time preference and show that net consumption is actually the vehicle by means of which time preference determines the rate of profit.¹¹

Alongside net consumption, I also develop the very important role played in the determination of the rate of profit by the phenomenon of *net investment*, which I showed in Chapter 15 to be the result of differences between productive expenditure and costs.¹² In addition, I explain the influence of changes in the quantity of money and aggregate spending on the rate of profit, which influence I show to be integrally connected with the rate of net investment. Finally, on the basis of the knowledge gained concerning the determinants of the rate of profit, I demonstrate the existence of the virtual springs to profitability that I have referred to, which operate automatically to reestablish a significant positive rate of profit in the economic system following the end of a monetary contraction and the fall in wage rates and prices necessitated by the contraction.

The relationship between profits, on the one side, and net consumption plus net investment, on the other, is directly derivable from propositions already established in Chapter 15. In Chapter 15, I showed that profits, as sales revenues minus costs ($s - d$), are equal to $s_c + s_b - d$, namely, to receipts from the sale of consumers' goods plus receipts from the sale of capital goods, minus costs. I also showed not only that net investment is $B - d$, that is, productive expenditure minus those same costs, but also that productive expenditure itself equals $s_b + w_b$.¹³ It follows from these relationships that profits and net investment are very similar. This is because the equations for both incorporate not only the identical subtrahend d , namely, costs, but also include the identical component s_b in the minuend. It follows directly that the difference between profits and net investment is the difference between sales revenues and productive expenditure, which

reduces to the difference between s_c and w_b , that is, to the difference between receipts from the sale of consumers' goods and the payment of wages by business, which difference is net consumption. In terms of simple algebra,

$$\begin{aligned} p - I &= \\ s_c + s_b - d - (s_b + w_b - d) &= \\ s_c - w_b. \end{aligned}$$

It follows, of course, that if profits minus net investment equals net consumption, *profits are equal to the sum of net consumption plus net investment*.

The rest of this chapter can be understood essentially simply as an elaboration of the concepts of net consumption and net investment and their explanatory role in the determination of aggregate profit and the average rate of profit in the economic system.

The Problem of Aggregate Profit: Productive Expenditure and the Generation of Equivalent Sales Revenues and Costs

All business activity is carried on for the purpose of earning a profit. Yet the existence of the very phenomenon of profit in the economic system as a whole, that is, an aggregate profit—an excess of the sum of all profits over the sum of all losses—can appear difficult to explain. This is because productive expenditure, insofar as it constitutes revenue or income payments, bears an equivalent relationship to business sales revenues and to business costs. This is to say, productive expenditure can be understood as generating both an amount of sales revenues equal to itself *and* an amount of costs equal to itself, which would appear to imply that as far as productive expenditure by itself is concerned, the existence of an aggregate profit would be impossible, at least in the long-run, as a permanent phenomenon.

In elaboration of these points, the reader should consider the following facts. On the one hand, one major portion of productive expenditure—the demand for capital goods—is simultaneously business sales revenues. This part of productive expenditure and this part of business sales revenues are equal by identity, just as a side of one triangle is equal to that of another by identity when the two triangles share that same side. The two are identical because capital goods are sold by business enterprises as well as bought by business enterprises. For example, the demand made for steel sheet by an automobile company, or for flour by a baking company, is simultaneously a part of productive expenditure and a part of sales revenues. From the standpoint of the automobile company or baking company, it is a productive expenditure; from the standpoint of the steel company or flour company, it is sales revenue. From the standpoint

of the economic system as a whole, it is simultaneously both.¹⁴

At the same time, the remaining portion of productive expenditure, insofar as it constitutes revenue or income payments, is made up of wage payments, which, at least as a reasonable first approximation, can be assumed to be expended by their recipients in buying consumers' goods from business firms in the same accounting period.¹⁵

Thus, directly or indirectly, productive expenditure is to be understood as generating sales revenues equal to itself, and to do so essentially in the same accounting period.

In addition, however, productive expenditure generates business costs equal to itself. We know from Chapter 15 that many of these costs can appear in future accounting periods, indeed, decades in the future, insofar as the productive expenditures are made on account of plant and equipment with many years of useful life.¹⁶ Nevertheless, what must be the result in an economic system with a fixed quantity of money? In such an economic system, it would be reasonable to assume a fixed volume of productive expenditure and a fixed volume of business sales revenues. It would also seem reasonable to assume that at some point, aggregate business costs would rise to equality with the fixed amount of productive expenditure. Indeed, even if, for example, plant and equipment is depreciated over a fifty-year period, after fifty years of the same amount of spending for plant and equipment, annual depreciation charges on fifty years' worth of such plant and equipment rise to equality with the current annual spending for plant and equipment. Thus, the proposition would appear to be supported that costs deducted from business sales revenues must rise to equality with productive expenditure in conditions in which the same amount of productive expenditure is repeated over and over again, indefinitely.

But this last, of course, would mean that costs rise to equality with *business sales revenues* insofar as business sales revenues are generated only by productive expenditure. With costs equal to productive expenditure, and sales revenues equal to productive expenditure, both must be equal to each other. Things equal to the same thing are equal to each other. Thus, it would appear that in the conditions of a fixed quantity of money, and in which productive expenditure were the only source of business sales revenues, an aggregate profit simply could not exist as a permanent phenomenon. It would further appear that the average rate of profit in such conditions would have to be zero, at least insofar as productive expenditure were the only determinant of business sales revenues. This is because a zero amount of aggregate profit would mean a zero numerator in any calculation

of the average rate of profit.

Several times in the last two paragraphs, I used the word "appear," instead of making flat-out statements. This is because things would actually not be quite as bad for the rate of profit as I have just indicated. As I will show, even with a fixed amount of productive expenditure taking place year after year, indefinitely, it would always be possible to have some positive amount of profit. There could be profit equal to some positive amount of net investment, that is to say, to some continuing excess of productive expenditure over aggregate costs.¹⁷

Even under such conditions, however, a major negative implication would still be present. This would be that the average rate of profit in the economic system would be *continually falling*, in the direction of zero. This implication would exist, because insofar as profits correspond to net investment, the net investment constitutes an addition to the amount of capital invested. Thus even if every year there were the same amount of net investment and profit, that constant amount of profit would have to be spread ever thinner, over a continually growing volume of capital invested. Thus, the average rate of profit would be continually falling. For example, if the total capital invested in the economic system were initially 2,000 and there were 100 of profit corresponding to 100 of net investment, the average rate of profit would initially be 5 percent—that is, $\frac{100}{2,000}$. In the next year, however, it would be less than 5 percent—namely, $\frac{100}{2,100}$ —then still less, namely, $\frac{100}{2,200}$, and so on. This is because, as I say, the net investment of each year is added to the amount of accumulated capital.

There could be no possibility of the rate of profit holding up by virtue of net investment growing along with the growth in capital invested. This is because in the conditions of a constant amount of productive expenditure, which is the implication of a fixed quantity of money, the only way that net investment could grow would be by virtue of aggregate costs falling. To maintain a given rate of profit, aggregate costs would have to fall by ever increasing amounts—eventually, they would have to fall below zero and go on falling from there, to produce the ever growing amounts of net investment and profit that would be required to keep the rate of profit constant. But this, of course, is simply impossible.

For example, if the initial 100 of profit is the result of productive expenditure being 1,000 and costs being 900, then in the face of productive expenditure continuing to be 1,000, the only way the initial 5 percent rate of profit could be maintained would be if costs now fell to 895. This would provide 5 more of profit to accompany the 100 of additional capital resulting from 100 of net investment. Now, however, net investment becomes 105 and

capital grows from 2,100 to 2,205. To maintain a 5 percent rate of profit at this point, net investment of 110.25 would be required, which means that costs would have to fall to 889.75. In order for the rate of profit to be maintained at 5 percent, aggregate costs would have to fall at a rate equal to 5 percent compounded on a base of 100. This implies that at some point aggregate costs must fall to zero and then go into minus territory. These results, of course, are absolutely impossible. At some point, aggregate costs must stabilize, if not rise. This implies a fixed or falling amount of profit, while the amount of capital invested continues to grow.

Thus, we are left with the fact that in the conditions of a fixed quantity of money, insofar as productive expenditure alone is the source of business sales revenues, the average rate of profit in the economic system, if not actually at zero, must nevertheless be continually falling toward zero.

This brings me to the first major problem that I believe the theory of aggregate profit and the average rate of profit must solve, namely, *to explain how, in the conditions of a fixed quantity of money, the existence of a positive average rate of profit is possible on a long-run, permanent basis, and is so, moreover, without the rate of profit having continually to fall.*

2. Net Consumption and the Generation of an Excess of Sales Revenues Over Productive Expenditure

The answer to the question of how a positive average rate of profit can both exist and remain constant in the conditions of a fixed quantity of money and consequent fixed volume of productive expenditure is supplied by the concept of *net consumption*.

Net consumption, which we already know is the excess of the demand for consumers' goods from business over the demand for labor by business, is also the source of an equivalent excess of the *total* demand for the products of business over the *total* demand for factors of production by business.

The total demand for the products of business is the sum of the respective demands for consumers' goods and capital goods. Both of these demands are the source of business sales revenues. They are the only direct sources, inasmuch as every expenditure to buy the products of business must be made either for the purpose of making subsequent sales, in which case it is a demand for capital goods, or not for the purpose of making subsequent sales, in which case it is a demand for consumers' goods.¹⁸ The total demand for factors of production by business is the sum of the demand for labor by business—viz., the demand for producers' labor—plus the demand for capital goods.

Net consumption is the source of an equivalent excess of the total demand for the products of business over the total demand for factors of production by business because the addition of the demand for capital goods to the demand for consumers' goods in the minuend, and to the demand for labor by business in the subtrahend, leaves the amount of the inequality unchanged. Equals added to unequals do not affect the amount of the inequality. Thus, if net consumption is the difference between the demand for consumers' goods from business and the demand for labor by business, it is equally the difference between the total demand for the products of business and the total demand for factors of production by business. Furthermore, inasmuch as the total demand for the products of business is identical with total business sales revenues, while the total demand for factors of production by business is identical with productive expenditure for labor and capital goods, net consumption is the source of an excess of the sales revenues of business over productive expenditure for labor and capital goods.

These conclusions can be expressed in terms both of the notation for demand employed in Chapters 13 and 14, and in terms of the notation for revenues and incomes employed in Chapter 15. In terms of the former, net consumption is $D_C - D_L$. In terms of the latter, it is $s_c - w_b$. If the demand for capital goods is expressed as D_K , then the total demand for the products of business equals $D_C + D_K$ while the total demand for factors of production by business equals $D_L + D_K$. Since D_K is present in both expressions, and thus disappears when one is subtracted from the other, the difference between the two expressions remains $D_C - D_L$. Thus, net consumption can be expressed as equal to the difference between $D_C + D_K$ and $D_L + D_K$.

In exactly the same way, if receipts from the sale of capital goods are stated as s_b , then, as we already know from Chapter 15, total business sales revenues equal $s_c + s_b$ while productive expenditure equals $w_b + s_b$. Since s_b is present in both expressions and disappears when one is subtracted from the other, the difference between sales revenues and productive expenditure reduces to $s_c - w_b$. Thus, net consumption can also be expressed as equal to the difference between $s_c + s_b$ and $w_b + s_b$.

I turn now to the substantive, as opposed to the purely mathematical, nature of net consumption. Considered substantively, and essentially, net consumption is *the consumption expenditure of businessmen and capitalists*, including under the latter head, the creditors of business firms as well as the owners of equity capital. (The ranks of the capitalists, of course, also include wage earners insofar as they possess capital. To the extent that the possession of capital enables the consumption of wage

earners to exceed their wages, the excess of their consumption is to be considered the consumption of capitalists and as contributing to net consumption.)

The essential sources of net consumption are the payment of dividends by corporations, the draw of funds by partners and proprietors from their firms, and the payment of interest by business firms. Of course, to the extent that such receipts are themselves saved and productively expended, they count as part of productive expenditure and the demand for factors of production by business. But some significant portion of these receipts is consumed. And to this extent, there is a demand for the products of business over and above the demand for factors of production by business, that is, a source of business sales revenues which has no counterpart in productive expenditure or costs and which thus makes possible an excess of sales revenues over productive expenditure and costs.

In the case of consumption expenditure out of dividends and draw payments, there is absolutely no counterpart whatever in productive expenditure or costs. Such payments do not represent a purchase, or even an exchange, of any kind. They are merely a transfer of funds from business firms to their owners. In the case of interest payments, there is a productive expenditure in the act of paying the interest, and this productive expenditure either immediately or later on shows up as a cost. However, these are productive expenditures and costs that, as I have explained, we deliberately ignore, in order to explain profits gross of interest cost. Consumption out of interest payments from business is a source of an excess of the demand for the products of business over the demand for actual, physical factors of production by business, that is, a source of an excess of sales revenues over the productive expenditure for capital goods and producers' labor. In this way, it is a source of an excess of sales revenues over costs on account of these physical factors of production, which, of course, is the profit we want to explain.

The role of net consumption in generating an excess of demand for the products of business over the demand for factors of production by business and thus an excess of business sales revenues over productive expenditure is illustrated in Table 16-1. The table, titled "The Components of the Demand for Factors of Production and Products," is divided into three columns. The leftmost column carries the heading "Demand for Factors of Production by Business (Productive Expenditure)," while the rightmost carries the heading "Demand for the Products of Business (Sales Revenues)." The second column of the table shows that item one under the former head is identically equal to item one under the latter head. Item one in both columns is, of course, the demand for capital goods. The second column of the table further shows that item two under the former head is equalled by item two under the latter head, that is, that the demand for labor and labor's (viz., wage earners') demand for consumers' goods are equal. This equality simply reflects the fact that the wage earners spend at least roughly the equivalent of their wages in buying consumers' goods from business. Finally, the second column of the table makes clear that item three of the third column, namely, "Businessmen's and Capitalists' Demand for Consumers' Goods," is the source of the excess of the demand for the products of business over the demand for factors of production by business, that is, of sales revenues over productive expenditure. For this item appears *only* as a source of demand for the products of business, without any counterpart in the demand for factors of production by business in column 1. Thus, it is a source of sales revenues without counterpart in productive expenditure or cost.

Table 16-2 provides a quantitative illustration of the role of net consumption in making the demand for the products of business exceed the demand for factors of production by business. Repeating the same headings as appeared in columns one and three of Table 16-1, it shows in its own first and third columns that item one under both heads, namely, the demand for capital goods

Table 16-1

The Components of the Demand for Factors of Production and Products

Demand for Factors of Production by Business (Productive Expenditure)	—IDENTITY—	Demand for the Products of Business (Sales Revenues)
1. Demand for Capital Goods		1. Demand for Capital Goods
2. Demand for Labor	—EQUALITY—	2. Labor's Demand for Consumers' Goods
	SOURCE OF EXCESS:	3. Businessmen's and Capitalists' Demand for Consumers' Goods

Table 16–2
The Components of Demand Numerically Illustrated

Demand for Factors of Production by Business (Productive Expenditure)		Demand for the Products of Business (Sales Revenues)		
1. Demand for Capital Goods:	500	—IDENTITY—	1. Demand for Capital Goods:	500
2. Demand for Labor:	300	—EQUALITY—	2. Labor's Demand for Consumers' Goods:	300
		SOURCE OF EXCESS:	3. Businessmen's and Capitalists' De- mand for Consumers' Goods:	200
Total Demand for Factors of Production by Business:	800		Total Demand for the Products of Business:	1,000

and the demand for capital goods, are identically equal at 500 monetary units. It shows that item two under both heads, namely, the demand for labor and labor's demand for consumers' goods, respectively, are equal at 300 monetary units. Finally, it shows item three, which appears in column three only, namely, "Businessmen's and Capitalists' Demand for Consumers' Goods," as 200 monetary units. When the two sides of the table are added, it is obvious that this last item is the basis of the fact that the total demand for the products of business—sales revenues—amounts to 1,000 monetary units, while the demand for factors of production by business—productive expenditure—amounts to only 800 monetary units.

In making possible an excess of the demand for the products of business over the demand for factors of production by business, net consumption is the basis of the aggregate profit of business in conditions in which costs are equal to the demand for factors of production by business. This is because if the demand for products exceeds the demand for factors of production, then the demand for products exceeds costs that are equal to the demand for factors of production, and does so to exactly the same extent. If one thing exceeds another, than it equally exceeds a third thing that is equal to that other. Thus, demand for products exceeds costs even if costs are fully equal to the demand for factors of production, because the demand for products exceeds the demand for factors of production. In exactly the same way, in the terminology of sales revenues and productive expenditure, sales revenues exceed costs even if costs are fully equal to productive expenditure, because—thanks to net consumption—sales revenues exceed productive expenditure.

Net consumption is the source of aggregate profit because it is the source of the demand for the products

of business being greater than the demand for factors of production by business, and thus of an excess of the demand for the products of business over costs that are equal to the demand for factors of production by business. In the terminology of sales revenues and productive expenditure, net consumption is the source of aggregate profit because it is the source of the excess of sales revenues over productive expenditure and thus of an excess of sales revenues over costs equal to productive expenditure. To the extent that the demand for the products of business exceeds the demand for factors of production by business, to identically the same extent does the demand for the products of business and the concomitant sales revenues of business exceed costs generated by and equal to the demand for factors of production by business. Equivalently, to the extent that sales revenues exceed productive expenditure, to identically the same extent do they exceed costs generated by and equal to productive expenditure. Thus, in being responsible for the excess of demand for the products of business over the demand for factors of production by business, or, equivalently, the excess of business sales revenues over productive expenditure, the consumption expenditure of businessmen and capitalists—net consumption—is the basis for the existence of a corresponding aggregate profit in the economic system. It is the basis of an exactly equal aggregate profit whenever the costs of business equal the demand for factors of production or, equivalently, productive expenditure.

Net consumption is what explains how it is possible for business in the aggregate regularly and consistently to sell for more than it buys, even under the conditions of an invariable money. It does so because insofar as businessmen and capitalists are themselves consumers, business firms are constantly injecting more funds into the market in toto to buy the products of business than

they expend for factors of production to produce those products. Receipts from the sale of the products of business in every year are generated by the *entire* expenditure of businessmen and capitalists, which includes their consumption expenditure as well as their productive expenditure; cost of production, on the other hand, tends to equal only their productive expenditure. Thus, the productive process is regularly accompanied by the existence of a demand for the products of business that is greater than the demand for the factors of production by business to produce those products. This is the cause of an excess of demand for the products of business over business costs and thus of business sales revenues over business costs.

To relate this discussion to the proposition that the demand for *A* is the demand for *A*, which I developed in the preceding chapter, we now see that the demand for products is not only not the same thing as a demand for factors of production, but regularly and consistently *exceeds* the demand for factors of production, and, in so doing, generates an amount of profit equal to that excess. The cause of the excess and thus the cause of the profit is the consumption of businessmen and capitalists. The amount of their consumption determines the amount of the excess of the demand for the products of business over the demand for factors of production by business and thus the amount of profit in conditions in which the demand for factors of production by business and the costs of business are equal.

Indeed, the net-consumption theory can be described as being contained in two propositions: (1) The entire demand for factors of production by business is directly (in the case of capital goods) or indirectly (in the case of labor) a source of demand for the products of business. (2) The demand for the products of business, however, is *not*—to the extent that it is a demand for consumers' goods—a demand for factors of production by business, but *exceeds* that demand by the consumption expenditure of businessmen and capitalists.

The role of net consumption in generating not merely an excess of demand for the products of business over the demand for factors of production by business, and thus of sales revenues over productive expenditure, but of an actual aggregate profit in the economic system, that is, an excess of sales revenues over *costs*, is depicted in Figure 16–1. This figure is an elaborated version of Figure 15–5, which showed the role of the demand for consumers' goods in determining national income under the conditions of an invariable money.¹⁹

Exactly as in Figure 15–5, Figure 16–1 shows a demand for capital goods of 500 and a demand for consumers' goods of 500 in every year from *Year 2* on. Thus it implicitly shows total business sales revenues as 1,000.

As in Figure 15–5, in response to these equal demands of 500, half the existing *IK* of capital goods and *IL* of labor are used to produce the next year's supply of capital goods, while the other half is used to produce the next year's supply of consumers' goods. Once again, the entire *IK* and *IL* are assumed to be used up in this way, and once again, the resulting product is shown as *IK* of capital goods plus *IC* of consumers' goods. Because the *IK* of capital goods used up in production is replaced out of production, each succeeding year has the same supply of capital goods as the preceding year. And in each succeeding year, of course, the *IK* of capital goods is joined by a fresh *IL* of labor. As in Figure 15–5, the 500 of expenditure for capital goods each year enters into the cost of the resulting output that constitutes the next year's supply of capital goods and consumers' goods.

The only difference between Figure 16–1 and Figure 15–5 is that the former introduces the sources of the 500 of demand for consumers' goods. It explains these sources in part as 300 of wage payments by business, which makes possible 300 of consumption on the part of wage earners. To this, it adds 200 of consumption on the part of businessmen and capitalists. Figure 16–1 also points out that the 300 of wage payments by business will result in 300 of cost on account of labor in the next year. The 300 of wage payments is transmitted to the cost of the following year's supply of capital goods and consumers' goods by way of the center "production boxes," so to speak.

This is the same transmission mechanism as existed in Figure 15–5, where 500 of cost on account of capital goods alone was transmitted, though it was not named as such at the time. The only difference is that now, instead of the production box from *Year 2* on having merely *IK* of capital goods at a cost of 500, and showing no cost for the *IL of labor*, the *IL of labor* carries a cost of 300 as well. The effect of the inclusion of the demand for labor by business is that the costs transmitted to the supplies of capital goods and consumers' goods available at the start of the following year are correspondingly larger. They are now respectively 50 percent of an 800-total outlay for factors of production instead of 50 percent merely of the 500 outlay for capital goods alone. Thus, the cost values of the capital goods and consumers' goods available at the start of *Year 3* and thereafter are 400 respectively, instead of 250 respectively, as was the case in Figure 15–5.

Figure 16–1 shows that while sales revenues in every year are 1,000, costs, which equal the productive expenditure of the year before, are only 800. Thus, an aggregate profit of 200 exists. In Figure 16–1, this is true explicitly for every year from *Year 3* on. In *Year 3*, sales revenues are 1,000, and costs, equal to the productive expenditure

1K OF CAPITAL GOODS, at a cost value of 400 on account of the capital goods and labor used to produce them, i.e., 50% of (500+300)

1C OF CONSUMERS' GOODS, at a cost value of 400 on account of the capital goods and labor used to produce them, i.e., 50% of (500+300)

In Response to 500 of Demand for Capital Goods. This 500 of demand for capital goods is simultaneously 500 of sales revenues to the sellers of the capital goods. It will also result in 500 of cost on account of capital goods to the buyers, next year, when they sell the products the capital goods are used to produce.

In Response to 500 of Demand for Consumers' Goods. This 500 of demand for consumers' goods is simultaneously 500 of sales revenues to the sellers of the consumers' goods. It results from the payment of 300 of wages by business, which the wage earners consume, plus 200 of consumption expenditure by businessmen and capitalists. The 300 of wages also result in 300 of cost on account of labor next year, when the products the wage earners help to produce are sold.

of Year 2, are only 800. Identically the same situation applies to every year thereafter. What generates an aggregate profit in Figure 16-1 is the fact that in every year, sales revenues are constant at 1,000, while productive expenditure is constant at 800, which last means that the costs of the following year are also 800, at which time sales revenues will again be 1,000. An aggregate profit exists in Figure 16-1 because of the excess of sales revenues over productive expenditure. This fact implies an equal excess of sales revenues over costs, once costs come to equal productive expenditure, which, in the case of Figure 16-1, of course, is the very next year. To say it as simply as possible, the excess of sales revenues over productive expenditure is what explains the excess of sales revenues over costs equal to productive expenditure.

And, of course, what in turn explains the excess of sales revenues over productive expenditure in Figure 16-1 is net consumption—the consumption expenditure

of businessmen and capitalists themselves. This expenditure, as Figure 16-1 further illustrates, is a source of sales revenues, but has no counterpart in productive expenditure or, therefore, in costs, which are generated by past productive expenditure, in this case, the productive expenditure of the year before.²⁰

Table 16-3, which is based on the data of Figure 16-1, presents a further quantitative depiction of the role played by net consumption in determining aggregate profit. It shows that in each year, Figure 16-1's productive expenditure of 800 is the cause of equivalent costs that show up as a deduction from sales revenues in the following year. This is shown by the arrows sloping down and to the right, connecting each year's 800 of productive expenditure to the next year's 800 of costs. The table also shows each year's 800 of productive expenditure as the source of equivalent sales revenues in the same year as that in which the productive expenditure takes place. This is shown by the two straight lines, a short one going

Table 16-3
Productive Expenditure, Costs, and Sales Revenues
—the Elements Generating Profit in Figure 16-1

Year	Productive Expenditure	Costs	Sales Revenues	Profit	Net Consumption
1	NA	NA	NA	NA	NA
2	800	NA	1,000	NA	200
3	800	800	1,000	200	200
4	800	800	1,000	200	200
5	800	800	1,000	200	200
...
N	800	800	1,000	200	200

The table above shows that the productive expenditure of each year shows up as equivalent costs in the next year. It also shows that a repetition of the same amount of productive expenditure in the next year generates sales revenues equal to those costs. Finally, it shows that the excess of sales revenues over costs is determined by net consumption, which is essentially the consumption expenditure of businessmen and capitalists. (As in Figure 16-1, on which the table is based, quantitative data are not available for Year 1, with the result that neither costs nor profits can be calculated for Year 2.)

down and a longer one going across to the right, that culminate in an arrow pointing upward to the 1,000 of sales revenues of each year. The source of the sales revenues being 1,000 while productive expenditure is 800 is clearly the 200 of consumption expenditure on the part of businessmen and capitalists in each year, which is represented by the item "Net Consumption." When the 200 of sales revenues generated by this 200 of consumption expenditure are added to the 800 of sales revenues generated by the 800 of productive expenditure, total sales revenues become 1,000. The generation of 1,000 of sales revenues is depicted by the confluence of the two vertical arrows, one representing the 800 of productive expenditure in the year, and the other representing the 200 of consumption on the part of businessmen and capitalists—the item "net consumption." (Two additional straight lines, again, a short one going down and a longer one going across, but this time to the left, connect net consumption to the second arrow pointing up to sales revenues.) Thus, what enables sales revenues to be 1,000 while productive expenditure and costs are 800 is the consumption expenditure of the businessmen and capitalists in the amount of 200. This consumption expenditure is what makes sales revenues exceed productive expenditure by 200 and thus costs by 200, with the result that 200 of profit is generated.

In order to show the determination not only of the aggregate amount of profit but also of the average rate of profit in the economic system, it is necessary to add yet some further elaboration to the diagrammatic analysis we have been pursuing since Chapter 14. This is done in Figure 16–2, which is an elaboration of Figure 16–1.

In Figure 16–2, each year is described in terms of a series of rows depicting the "Opening Assets of Business," "Transactions," and "Production," respectively. We are already familiar with all of these elements from Figure 16–1, even though they were not explicitly labeled as such at the time. In Figure 16–1, each year began with what in essence was a partial description of the opening assets of business in that year, namely, the quantity *IK* of capital goods and the quantity *IC* of consumers' goods. Indeed, in Figure 16–1, starting in *Year 3*, these quantities were shown as possessing cost values of 400 monetary units each. These cost values were derived on the basis of the transactions and production that took place in the preceding year. Figure 16–1 showed that starting with *Year 2*, 500 monetary units were expended in buying the *IK* of capital goods every year, and 300 monetary units were expended in buying the *IL* of labor that was available every year for production. The fact that 800 monetary units in all were thus paid for the factors of production in each year and that then those factors of production were used 50 percent in

producing capital goods and 50 percent in producing consumers' goods, was what underlay the respective cost values of 400 for the capital goods and consumers' goods appearing at the beginning of *Year 3* and all subsequent years.

In Figure 16–2, identically the same kind of "production box" appears in each year as appeared in Figure 16–1. The only difference is that in Figure 16–2 it is labeled as production, in a distinct row. Transactions are described graphically in Figure 16–2, whereas in Figure 16–1, they were described verbally. The only substantive difference between Figures 16–2 and 16–1 is that in Figure 16–2 the opening assets of business that are described in the first row under each year, are not only *IK* of capital goods and *IC* of consumers' goods, as before, but also a sum of money—namely, 1,000 units of cash. In addition, the capital goods and consumers' goods are shown bearing their specific monetary cost values, namely, 400 monetary units each, starting with *Year 1*, rather than *Year 3*. The cost values shown in the opening assets of *Year 1* are derived by treating *Year 1* as representing exactly the same set of conditions as prevailed in all the years of Figure 16–1 from *Year 3* on. In Figure 16–2, *Year 1* should be understood as representing a year following an indefinite number of previous years just like it and like those that follow it, and as being labeled *Year 1* only from the perspective of being the first year singled out for analysis.

The cash, and the various transactions that it finances, are shown in distinct, gray-colored boxes. The transactions, of course, appear in the second, transactions row under each year. They represent expenditure of the money originally held as an opening asset of business, in the first row, namely, the asset "1,000 units of Cash to Be Paid Out." This sum, and the demand for the goods and services of business that it finances every year, are both assumed to be invariably fixed at 1,000 units of money.

For the sake of simplicity, it is assumed in Figure 16–2 that all transactions take place on the first day of each year, whereafter the various parties retire to engage in the process of producing the output that will become available and will be sold on the first day of the following year.²¹ Thus, it is assumed that on the first day of each year, business buys its entire supply of capital goods for the year and pays all the wages and sources of net consumption that it pays for the entire year, and that the recipients of these sums turn around and expend them on that same day in buying a year's supply of consumers' goods from business. This assumption permits dealing with all transactions in the economic system at one fell swoop and then turning to the process of production that ensues with the capital goods and labor that have been purchased. The process of production, of course, is de-

Figure 16-2
The Elements Determining the Average Rate of Profit

pictured in the production row under each year, as I have already said. As in Figure 16–1, the process of production of each year culminates in the supply of capital goods and consumers' goods contained in the opening assets of business at the start of the following year. Just as before, it is assumed that all capital goods and labor used in production in any year are fully used up in producing the output that will be sold at the start of the following year. The assumption also continues to be made, of course, that the factors of production in each year are used in accordance with the relative demands for capital goods and consumers' goods that are expected to exist in the following year, and that these expectations are correct.

In Figure 16–2, in *Year 1* and in every succeeding year, 500 units of cash are expended by business firms in buying capital goods, just as was the case in Figure 16–1 from *Year 2* on. The origin of the demand for capital goods in the opening cash holding of business is indicated by the small arrow which connects the lower left-hand portion of the gray box “1,000 Units of Cash to Be Paid Out” to the upper right-hand portion of the gray box “Demand for Capital Goods: 500.”

The firms that expend the 500 for capital goods receive into their possession *IK* of capital goods out of the opening assets of business. That *IK* of capital goods will then serve these firms in the process of production depicted in the production row. The conveyance of the *IK* of capital goods from the opening assets of business to their subsequent use in production is depicted by a series of three straight lines running from the box representing *IK* of capital goods as an opening asset of business, around the box “Demand for Capital Goods: 500” in the transactions row, and culminating in an arrow pointing to the production box in the production row. Thus, as in Figure 16–1, the *IK* of capital goods enters into the process of production with a cost value of 500, which is the sum of money that was paid for these capital goods in the transactions row.

At the same time that business firms are buying *IK* of capital goods for use in further production, business firms are, of course, also selling that *IK* of capital goods. Here, however, Figure 16–2 goes beyond Figure 16–1 in that it shows not only that business in the aggregate is simultaneously both a buyer and a seller of capital goods to the same extent, but also the corollary fact that from the perspective of business as a whole, insofar as the asset “cash” is drawn down in the purchase of capital goods, it is simultaneously replenished in the sale of capital goods. Thus, to this extent, the cash holding of business in the aggregate remains unchanged, and cash will be available to finance the fresh transactions of the following year. This is depicted by a combination of two arrows. First, there is the one running down and to the left from

the gray box labeled “1,000 Units of Cash to Be Paid Out” and over to the gray box labeled “Demand for Capital Goods: 500” in the transactions row. And then there is the one that runs vertically upward from this latter box to the white box representing the *IK* of capital goods in the opening-assets-of-business row. This second arrow, shows the return to business of the cash paid out by business in the purchase of capital goods.

The opening cash holding of business is also assumed to finance total wage payments of 300 units of money and net consumption in the amount of 200 units of money, which, in combination, in turn make possible the demand for consumers' goods of 500 units of money. Two small arrows running from the bottom of the box “1,000 Units of Cash to Be Paid Out” to the top of the gray box “Wages: 300 + Net Cons.: 200” indicate the origin of wage payments and the sources of net consumption in the opening cash holding of business. The depiction of wage payments by business together with net consumption as the source of demand for consumers' goods from business is achieved by means of an ellipse drawn around wages plus net consumption, to which is attached a straight line sloping downward and to the right and that culminates in a vertical arrow pointing up to the gray box representing the demand for consumers' goods. The up and down arrows running between the gray demand-for-consumers-goods box and the white consumers-goods box signify that money is turned over to business in exchange for the consumers' goods and that these goods are conveyed into the possession of their buyers.

Thus, in Figure 16–2, as in Figure 16–1, in financing both the demand for capital goods and the demand for consumers' goods, business itself is shown as the source, direct or indirect, of the entire demand for its products, that is, of all of its own sales revenues. At the same time, however, it is also shown that because the cash that business draws down in making wage and payments and in providing the sources of net consumption is returned to it in the form of receipts from the sale of consumers' goods, business will have the same 1,000 units of cash available as an opening asset in the next year as it had in the present year. This is because the 500 of cash expended in wage payments and in providing the sources of net consumption which is returned in 500 of receipts from the sale of consumers' goods, is joined to the 500 of cash expended in the purchase of capital goods and simultaneously returned in the sale of capital goods.

Thus, what Figure 16–2 shows is business making 1,000 of total outlays, on the basis of which it obtains 1,000 of total sales revenues, and, in the receipt of the sales revenues, the return of all the cash that it has laid out.

As in Figure 16–1, the IL of labor that business buys for its 300 payment of wages, shows up in the production box at its cost value of 300. This is depicted by the ellipse drawn specifically around “Wages: 300” and connected to the production box by a straight line sloping downward and to the left and culminating in a horizontal arrow pointing right, to the production box. Thus, as in Figure 16–1, the production box shows both IK of capital goods at 500 plus IL of labor at 300.

Figure 16–2 provides all the elements necessary for the explanation not only of the generation of 1,000 of aggregate sales revenues and 800 of cost on account of capital goods and labor, and thus 200 of aggregate profit, as did Figure 16–1. It also provides the further information necessary for a precise calculation of the average rate of profit in the economic system in every year. It does so in providing knowledge of the total value of the opening assets of business each year, which is shown to be 1,800 monetary units. This amount, which is the sum of the 400 cost value of the IK of capital goods on hand, plus the 400 cost value of the IC of consumers’ goods on hand, plus 1,000 of cash, represents the total capital invested in the economic system. It is, in effect, the sum of cash together with the cost value of inventory and net plant and equipment.²² Thus, it follows that the average rate of profit in the economic system described in Figure 16–2 is precisely $200/1,800$, or 11.1 percent. This is the amount of profit earned in the economic system, divided by the amount of capital invested in the economic system, which latter, as I say, is what the sum of the asset values I have just named represents.²³

Inasmuch as the amount of profit in an economic system with an invariable money, such as that described in Figure 16–2, tends to equal the amount of net consumption, it follows that the rate of profit in such an economic system tends to equal *the rate of net consumption*. The rate of net consumption is the rate borne by the amount of net consumption to the total capital invested in the economic system. Whatever this rate may be, precisely that is what the average rate of profit in such an economic system must tend to be. In Figure 16–2, for example, the rate of profit of $200/1,800$ is precisely equal to the rate of net consumption, which is also $200/1,800$. This is an essential finding of this section, to which reference will be made in subsequent pages.

Net Consumption: Its Other Sources, Wider Meaning, and Relationship to the Saving of Wage Earners

An excess of consumption over wage payments is capable of being caused by factors other than consumption out of dividends, draw, and interest payments, though these are its regular and most important sources and tend to be the only sources in an economic system with an

invariable money. Consumption made possible by business firms’ repayment of debt or retirement of outstanding shares of stock is also capable of contributing to consumption spending being greater than wage payments, and thus of causing sales revenues to be greater than productive expenditure and costs. Consumption out of newly created money is likewise capable of so contributing. So too is consumption by wage earners that is made possible by extensions of credit from business firms and which permits their consumption to be greater than their wages. In addition, it should be realized that to whatever extent the total consumption expenditure of wage earners turns out to be less than wages, the excess of consumption over wages is correspondingly reduced.

The term net consumption embraces *all* sources of consumption in excess of wage payments, and thus of sales revenues in excess of productive expenditure. It also takes into account any possible diminution of this excess that might be caused by the consumption of wage earners being less than wages. Net consumption is simply the total spending to buy consumers’ goods in the economic system, minus wage payments by business firms. It is, as I say, the demand for consumers’ goods minus the demand for labor by business.

It must be pointed out that net consumption equals not only the demand for consumers’ goods minus the wages paid by business firms, but *all* of consumption, insofar as it constitutes sales revenue or wage income, minus *all* of wages. This is because the total of such consumption differs from the demand for consumers’ goods only by the addition of wage payments made by consumers—viz., by the w_c of Chapter 15.²⁴ By the same token, the total of wages differs from the wages paid by business firms by those very same wages paid by consumers. Thus,

$$\begin{aligned} \text{Net Consumption} &= s_c - w_b = \\ & s_c + w_c - (w_b + w_c) = C - w. \end{aligned}$$

Again, equals added to unequals do not affect the amount of the inequality.

The fact that net consumption can be stated as consumption minus wages provides further confirmation for the fact that aggregate profit tends to equal it. This is because the proposition that profit tends to equal consumption minus wages is a corollary of the previously established proposition that national income tends to equal consumption. National income, of course, is essentially profit plus wages. It should not be surprising therefore, that profit, which necessarily equals national income minus wages, also tends to equal consumption minus wages, i.e., net consumption. That is, if $p + w$ tends to equal C , then p tends to equal $C - w$. As I have said, the main sources of net consumption (and in an economy

with an invariable money, virtually the only sources worth speaking about in the long run) are dividends, draw, and interest payments. In an economy with an invariable money, net consumption and the consumption of businessmen and capitalists are virtually one and the same. In an economy with an expanding quantity of money, net consumption tends to be somewhat larger than this, reflecting as well consumption spending out of new and additional money. As I have indicated, such net consumption might also include consumption spending by wage earners in excess of wage payments, which is financed by continuing net extensions of credit accompanying the increase in the quantity of money.²⁵

It is almost certainly the case, however, that the influence of a growing quantity of money and therefore rising wage incomes is to lead wage earners to increase their accumulated savings, in order to maintain a certain balance with their rising incomes. In connection with this fact, it must be stressed that it would be an error to assume that consumption out of wages tends to be less than wages to the extent that wage earners save. Most of the savings of wage earners goes to finance loans for various forms of consumption, above all, home mortgage loans, which are the leading asset of savings banks and life insurance companies, which, of course, in turn are the leading vehicles for wage earners' saving. Such savings of wage earners are themselves consumed and do not in any way diminish consumption expenditure. They merely transfer it from those who earn the wages to those who borrow the savings made out of wages. The same point, of course, applies to savings of wage earners that are used to finance such things as installment loans for the purchase of personal automobiles and all the various home appliances, and to vacation loans.²⁶

Of course, to an important extent, the savings of wage earners are used to finance productive expenditures by business firms, and a significant number of wage earners use their savings to launch their own businesses. But when the extensions of credit to wage earners that come from business firms—such as mortgage and installment loans financed by business firms' time deposits at commercial banks—are offset against such savings by wage earners, it is probable that the whole or practically the whole of wages has an equivalent in consumption on the part of wage earners, irrespective of the fact that the wage earners are engaged in saving.

It should be clearly understood that net consumption explains profits not only in the production and sale of consumers' goods, but equally in the production and sale of capital goods. It is not accidental that in Figure 16–2, the production of capital goods is fully as profitable as the production of consumers' goods. (With the cost value

of both the capital goods and the consumers' goods at 400 each, and sales revenue in both cases at 500, the profit in both cases is 100.) The existence of net consumption operates to make the demand for goods at every stage of the productive process exceed the demand for the factors of production required to produce those goods. This is because consumption on the part of businessmen and capitalists engaged in the production of capital goods makes the demand for factors of production at every stage of capital goods production less than the demand for the resulting capital goods at that stage.

The uniformity-of-profit principle cooperates in producing this effect. If the rate of profit is higher in any branch of production than in the rest of the economic system, then a tendency exists to withdraw capital from the less profitable branches and invest it in the more profitable branches. This results in a reduction in productive expenditure in the less profitable branches and an increase in productive expenditure in the more profitable branches.

For these reasons, productive expenditure tends to be less than sales revenues throughout the economic system, and by no means merely in the production of consumers' goods alone.

Confirming the Critique of the Exploitation Theory

It should be obvious by now that in the conditions of an invariable money, the higher is net consumption, the higher is the amount and rate of profit and that the lower is net consumption, the lower is the amount and rate of profit.

To illustrate this fact, let us assume that businessmen and capitalists, instead of expending 800 monetary units for factors of production and only 200 monetary units in their own consumption, as they do in Figures 16–1 and 16–2, reduce their expenditure for capital goods from 500 to 400 monetary units, and their expenditure for labor from 300 to 200 monetary units, thereby bringing their total expenditure for factors of production down to 600 monetary units while equivalently increasing their consumption expenditure from 200 to 400 monetary units. The demand for factors of production, therefore, is now only 600 monetary units, but the total demand for the products of business remains unchanged at 1,000 monetary units. This last is because the reduction in demand for capital goods is offset by a rise in the demand for consumers' goods on the part of businessmen and capitalists, and the reduction in the wage earners' demand for consumers' goods, resulting from the reduction in the demand for labor, is likewise offset. Thus, the difference between productive expenditure and sales revenue now rises to 400 monetary units, and, hence, aggregate profit now tends to rise to 400 monetary units. This

is because aggregate business costs will fall from 800, the previous level of productive expenditure, to 600, the new, lower level of productive expenditure. This is shown in Table 16-4.²⁷

Assuming an invariable money, and thus the demand for the products of business and therefore sales revenues to be unchanged at 1,000 monetary units, productive expenditure and the demand for factors of production by business could, conceivably, vary anywhere from zero to an amount not far short of the full demand for products, namely, 1,000 monetary units.²⁸ The height of the demand for factors of production depends on the height of net consumption. It will be the higher, the lower is net consumption, and the lower, the higher is net consumption. If net consumption—the consumption of businessmen and capitalists, who are the recipients of sales revenues—were to rise to equal the full amount of sales revenues, the demand for factors of production would fall to zero, and the rate of profit would rise to infinity. This is because in the absence of productive expenditure, the costs to be deducted from sales revenues would fall to zero. Thus the amount of profit would rise to equal the full amount of sales revenues. At the same time, as a further result of the absence of productive expenditure, the total of capital invested in the economic system would fall to zero. With productive expenditure zero, the wages paid in the production of products for sale would,

of course, also be zero. Precisely this was the case elaborated in Chapter 11, in the critique of the theoretical framework of the exploitation theory.²⁹ On the other hand, if net consumption were permanently to fall to as low a rate as is consistent with the existence of time preference—with the result that businessmen and capitalists consumed only the most modest portion of their sales revenues and used almost the full amount of them for productive expenditure—the demand for factors of production would rise almost to the point of sales revenues. The result would be that the costs deducted from sales revenues would rise almost to equal the sales revenues. This, together with the great accumulation of capital that would ensue, would mean that the amount and rate of profit would fall to a minimum.

Thus, it should now be apparent that in conditions of an invariable money, the rate of profit depends on the rate of net consumption. It should be equally apparent that insofar as this is the case, the rate of profit and economic progress and prosperity are *inversely related*, just as under an invariable money nominal national income and economic progress and prosperity are inversely related. This is because to the extent that the rate of profit depends on the rate of net consumption, a higher rate of profit signifies a lower relative demand for and production of capital goods. It also signifies a lower demand for labor relative to the demand for consumers' goods.

Table 16-4
A Rise in Profits Caused by a Rise in Net Consumption and Fall in Productive Expenditure

Year	Productive Expenditure	Costs	Sales Revenues	Profit	Net Consumption
1	600	600	1,000	400	400
2	600	600	1,000	400	400
3	600	600	1,000	400	400
4	600	600	1,000	400	400

The 600 of productive expenditure in the above table results from a fall in the demand for capital goods from 500 to 400 and in the demand for labor from 300 to 200, which are the consequence of a rise in net consumption from 200 to 400. Sales revenues continue to equal 1,000: while receipts from the sale of capital goods are 400 instead of 500 and receipts from the sale of consumers' goods to wage earners are 200 instead of 300, receipts from the sale of consumers' goods to businessmen and capitalists are now that much larger: 400 instead of 200. The effect is that the excess of sales revenues over productive expenditure is correspondingly increased. And since the productive expenditure of each year determines the costs deducted from sales revenues in the next year, profits are increased equivalently. In other words, the rise in net consumption results in unchanged sales revenues accompanied by equivalently lower costs of production deducted from those sales revenues.

3. The Net-Consumption Theory Further Considered

The net-consumption theory requires further elaboration. There are, first of all, a number of questions or objections not yet considered, which are almost certain to be raised against it. And then there is the necessity of tracing net consumption back to more fundamental forces.

Why Businessmen and Capitalists Cannot Arbitrarily Increase the Rate of Net Consumption and the Rate of Profit

A question that can be raised in connection with the net-consumption theory is that if the consumption of the businessmen and capitalists is, at least in part, the cause of the profit they earn, why do they not deliberately increase their consumption and thereby increase the rate of profit?

To answer this question, we need only distinguish between the effect of an increase in the consumption of an individual businessman or capitalist on the profit which *he* will earn and on the profit which *all businessmen and capitalists taken together* will earn. An increase in consumption on the part of an individual businessman or capitalist operates to increase the amount of profit in the economic system as a whole, but, at the same time, to reduce the capital of the individual businessman or capitalist in question to a much greater degree, and thereby to reduce the amount of profit which *he* will earn.

For example, let us assume that, just as in Figure 16-2, the sum of all capitals in the economic system as a whole is 1,800 monetary units and that the aggregate amount of profit is 200 monetary units, equal to 200 monetary units of net consumption. Let us also assume that in this economic system some particular individual businessman or capitalist possesses a capital of 18 monetary units. (This is obviously an enormously large businessman or capitalist, possessing as he does an amount of capital equal to a full 1 percent of the entire capital of the economic system.) If we further assume that this businessman or capitalist possesses the average degree of skill and efficiency in investing his capital, he will earn 2 monetary units in profit on his capital, for that is the product of the average rate of profit of $\frac{200}{1,800}$, or $\frac{1}{9}$, times his individual capital of 18.

Now let us assume that he increases his consumption by 1 monetary unit. In the economic system as a whole, the amount of net consumption and the amount of profit will rise to 201 monetary units, but the capital of this individual businessman or capitalist will have fallen to 17 monetary units, with the result that *he* earns a smaller amount of profit than before. This is because the now very slightly higher average rate of profit that our indi-

vidual businessman or capitalist earns of $\frac{201}{1,799}$, when applied to his reduced capital of 17 monetary units, yields an amount of profit of only 1.9 monetary units, as compared with the 2 monetary units of profit that he originally earned. The situation of this individual businessman or capitalist is that he now earns a profit of 17 times $\frac{201}{1,799}$ instead of 18 times $\frac{200}{1,800}$. He earns less profit because his capital falls in the ratio of 17 to 18, while aggregate profit rises only in the much smaller ratio of 201 to 200. Thus, his individual share of aggregate profit falls by more than aggregate profit increases. And if, as is more likely the case, our individual businessman or capitalist possessed a capital of one-tenth of 1 percent of the capital of the economic system rather than 1 percent, that is, 1.8 of capital rather than 18 of capital, the reduction in his profits resulting from increasing his consumption by one monetary unit would be even more pronounced. In that case, instead of earning 1.8 times $\frac{200}{1,800}$, he would earn $\frac{1.8}{10}$ times $\frac{201}{1,799}$. His own individual capital would be cut more than in half, while he succeeded in raising the average rate of profit only very slightly.

The principle here is that while an individual businessman or capitalist can to some extent succeed in raising the general, average rate of profit by increasing his own consumption, he reduces his own individual capital to a greater degree. The effect of his action, therefore, would be to benefit other businessmen and capitalists while harming himself. Thus, businessmen and capitalists are not in a position to attempt deliberately to raise the rate of profit by increasing their own consumption.

The Net-Consumption Rate and the Gravitation of Relative Wealth and Income

The fact that businessmen and capitalists cannot arbitrarily raise their own individual rates of profit by virtue of increasing their consumption, has major implications for the question of what determines the growth and decline of the fortunes of individual businessmen and capitalists relative to one another.

In an economic system with an invariable money, the general or average rate of profit is determined by the economy-wide—necessarily *average*—rate of net consumption. Individual businessmen and capitalists, however, consume at widely varying *individual* rates—some well above the rate of net consumption and some substantially below it. If all businessmen and capitalists had the same productive ability, they would all earn the same rate of profit, as determined by the rate of net consumption. Those individual businessmen and capitalists whose consumption relative to their capitals was below average, would save and accumulate capital, while those individual businessmen and capitalists whose consumption rel-

ative to their capitals was above average would decumulate capital.

For example, in the conditions of Figure 16–2, businessmen and capitalists of average productive ability would earn the average rate of profit of 11.1 percent, which is equal to the net-consumption rate. The businessmen or capitalists of average productive ability whose own individual rates of consumption relative to accumulated capital happened to be 11.1 percent would neither accumulate nor decumulate capital. Those individual businessmen or capitalists of average productive ability whose individual rates of consumption relative to accumulated capital were less than 11.1 percent would accumulate capital. Those whose individual rates were above 11.1 percent would decumulate capital. For example, businessmen and capitalists with a 7 percent rate of consumption relative to accumulated capital would accumulate additional capital at the rate of approximately 4 percent a year. By the same token, those with a 15 percent rate of consumption relative to accumulated capital would decumulate capital at the rate of approximately 4 percent a year.

It follows from this discussion that the rate of net consumption prevailing in the economy as a whole tends to be governed by the rates of consumption relative to accumulated capital of those individual businessmen and capitalists *whose rates are the lowest*. In the nature of the case, with each passing year, these individuals tend to come into possession of a larger and larger proportion of the total capital of the economic system, while those with above-average rates of consumption progressively deprive themselves of capital. Thus the lower rates of consumption come to prevail on an ever growing proportion of the total capital of the economic system and more and more to govern the overall ratio of net consumption to capital.

This fact, incidentally, implies that even if there were somehow a conspiracy of a large number of businessmen and capitalists to raise the rate of profit by virtue of increasing their consumption, the conspiracy could not succeed for very long. This is because even if these businessmen and capitalists possessed the far greater part of the capital of the economic system and were in a position temporarily to increase their own profits by increasing their consumption, any businessman or capitalist who stood outside the conspiracy would earn that same higher rate of profit and, at the same time, thanks to his lower rate of consumption relative to accumulated capital, would be able rapidly to increase his capital relative to that of the members of the conspiracy. The effect of any such conspiracy would simply be to destroy its members and to replace them with businessmen and capitalists who consumed less relatively to their accumu-

lated capitals. Always, as far as it is governed by the rate of net consumption, the rate of profit tends to be governed by the lowest rates of consumption relative to accumulated capital.

As we already know, and shall see further, net consumption is not the only determinant of the rate of profit. The fact that it is not makes the rate of profit higher than the rate of net consumption. But even so—assuming they are of average productive ability and therefore earn the average rate of profit—those businessmen and capitalists with rates of consumption that are below the net-consumption rate tend to expand relatively to those businessmen and capitalists whose rates of consumption are above the net-consumption rate. For example, it may be that the net-consumption rate in the economic system is 3 percent, say, while the average rate of profit is 6 percent, the difference being the result of the operation of factors other than net consumption (notably, net investment). In such conditions, businessmen and capitalists of average productive ability will earn the average rate of profit of 6 percent. Those with rates of consumption relative to accumulated capital of less than 3 percent will save and invest and thus increase their capital at a more rapid rate than those with rates of consumption relative to capital of greater than 3 percent. A businessman or capitalist with a rate of consumption relative to capital of 2 percent, say, will be able to save and invest two-thirds of his 6 percent rate of profit. He will increase his capital at a 4 percent annual rate. By the same token, a businessman or capitalist with a rate of consumption relative to accumulated capital of 4 percent, say, will be able to save and invest only one-third of his 6 percent rate of profit. He will be able to accumulate additional capital at only a 2 percent annual rate. Thus, just as under the conditions of an invariable money, those businessmen and capitalists with the lowest rates of consumption relative to accumulated capital must tend increasingly to prevail, for they will steadily be increasing the size of their capitals relative to the capitals of businessmen and capitalists with higher rates of consumption relative to accumulated capital.

Of course, individual businessmen and capitalists differ widely in their productive abilities. Those with above-average productive ability earn higher rates of profit than those with below-average productive ability, which latter may actually incur losses. These differences in the individual rates of profit that are earned are no less important in determining the growth or decline of the fortunes of individual businessmen and capitalists. The full principle determining the growth or decline of the fortunes of individual businessmen and capitalists relative to one another must be stated as follows: *The relative wealth and income of individual businessmen and capitalists*

tends to grow to the degree that their productive ability is above average and their rate of consumption relative to accumulated capital is below average, and to decline to the degree that their productive ability is below average and their consumption relative to accumulated capital is above average.

In an economic system with an invariable money, the wealth and income of the businessmen and capitalists of below-average productive ability and/or above-average rates of consumption would tend to decline absolutely in terms of money. In an economic system with an increasing quantity of money and volume of spending, the monetary value of the wealth and income of such businessmen and capitalists need not decline in absolute terms, but it will still decline to the same extent in relative terms. Thus, for example, instead of the fortunes of the heirs of such great businessmen and capitalists as John Jacob Astor and Cornelius Vanderbilt shrinking from tens of millions to tens of thousands, while the fortunes of new great businessmen and capitalists correspondingly rise, the decline of the former is less and the rise of the latter correspondingly greater in terms of money. If the increase in the quantity of money and volume of spending is great enough, it will be common to have cases in which there is no absolute decline in family fortunes in monetary terms. But then the rise in the fortunes of the newcomers in terms of money is correspondingly greater still.³⁰

Irrespective of the nature of the monetary system, whether it is invariable or expanding, the present discussion confirms the previous discussion of economic inequality in Chapter 9 of this book, concerning the earning of fortunes in a capitalist economy.³¹ Fortunes are earned on the basis of above-average productive ability coupled with below-average rates of consumption relative to accumulated capital. They are made by earning high rates of profit and saving and reinvesting the far greater part of the profits. Relative wealth and income in a capitalist economy always gravitates to those who are most productive and most provident. The further effect is the most rapid possible increase in the absolute amount of real physical wealth, which, of course, is to the benefit of all.

Accumulated Capital as a Determinant of Net Consumption

A second question or objection that may be raised in connection with the net-consumption theory is that it places the consumption of the businessmen and capitalists ahead of their receipt of profit and thereby reverses cause and effect. To be sure, this is the very opposite of the way in which one usually approaches the relationship between consumption and income. One usually places

income before consumption. However, in the case of the consumption of the businessmen and capitalists, the procedure of the net-consumption theory is perfectly proper. This is because businessmen and capitalists possess not only their incomes but also, first and foremost, their *capitals*. The consumption of businessmen and capitalists is not governed by their incomes, but by their exchangeable wealth, that is, by the sum of their incomes and capitals together. At any given time, their incomes constitute only a small fraction of this total, and their capitals the overwhelmingly greater part. This is true typically even of a whole year's income. It is even more true insofar as the income earned by businessmen and capitalists is itself conceived as a sum of exchangeable wealth, which it is in the form in which it is actually obtained, such as a quarterly dividend check, or the profits of a particular month or even week or day. It is probable that a decline in the incomes of businessmen and capitalists affects their consumption only to the extent that it represents a decline in this total of their exchangeable wealth.

The consumption of businessmen and capitalists in the real world is never in fact greatly affected by the height of their current incomes. Business enterprises continue to pay interest on loans and, often, dividends on stock, even when these payments are not covered by current earnings. Furthermore, it should be recalled that in addition to dividend and interest payments on the part of business enterprises, funds for consumption can be obtained by businessmen and capitalists by means of the redemption of bond and stock issues by business firms. Imagine the case of a stockholder whose enterprise is currently paying no dividends. If elsewhere in the economic system, a bond or stock issue is redeemed, the stockholder in question can sell a portion of his holdings to these other bond or stockholders whose holdings have been redeemed, and then consume the proceeds. For the bond or stockholders whose holdings have been redeemed will almost certainly wish to reinvest most of the funds they receive, and in so doing they disperse the funds they have received to securities owners throughout the economic system and thereby provide funds for consumption even in cases in which no interest or dividend income has been received. And even apart from any current redemption of securities by business firms, there are always funds in the market available to buy the security holdings of any given individual.

In connection with this discussion, it is worth noting that in the worst years of the Great Depression—1932 and 1933—when total profit income in the United States was approximately \$11 billion and \$10 billion respectively, net consumption was approximately \$17 billion and \$15 billion respectively, the difference between prof-

its and net consumption being accounted for by negative net investment in the respective amounts of approximately \$6 billion and \$5 billion.³²

It is perfectly reasonable that the consumption of businessmen and capitalists should be governed primarily by their capitals rather than by their incomes. Imagine the case of an individual who possesses a capital of \$10,000,000, and who customarily earns \$500,000 in income on this capital, which, for the sake of simplicity, we assume is all available to him on the first day of the year, having been paid to him at the very end of the year before.³³ Let us assume that he is in the habit of consuming his entire income, and that suddenly this income ceases. Previously, on the first day of each year, he possessed \$10,500,000, of which he consumed \$500,000 over the course of the year, and employed \$10,000,000 to make provision for the future, in the form of investments. Now, on the first day of this year, he possesses only \$10,000,000. Will his consumption be appreciably different? Almost certainly not.

If he possesses \$10,000,000 instead of \$10,500,000, his consumption will be only slightly affected. He will still be a multimillionaire and will still live like one. The fact that he has no income will not have anything remotely like the significance it has for an individual with little or no capital. His loss of \$500,000 of income will be taken out both on his current consumption and on his provision for the future, and probably, on average, in the same proportions as he previously consumed and made provision for the future. What is of significance for such an individual is not the decline in his income, but the much more modest decline in the total of his income as obtained plus his capital. The measure of this decline is not 100 percent, as it is in the case of his income, but something less than 5 percent. Rather than expecting his consumption to fall to zero because his income has fallen to zero, it is much more reasonable to expect that both his consumption and his provision for the future will fall in proportion to the fall in his overall exchangeable wealth, that is, in the ratio of $\frac{\$10,000,000}{\$10,500,000}$, which of course is $\frac{20}{21}$. Thus, in an average case, he would now most likely consume on the order of \$475,000 over the course of the year, and employ on the order of \$9,525,000 to make provision for the future. For these sums stand in the same respective proportions to \$10,000,000 as do \$500,000 and \$10,000,000 to \$10,500,000.

Thus, even if the income of businessmen and capitalists were to completely disappear for some reason, if they still possessed their capitals, their consumption would continue almost unchanged and very soon restore the rate of profit to its former height insofar as it depends on the rate of net consumption. This is because, given the existence of net consumption and its accompanying excess

of sales revenues over productive expenditure, the only way that profit could not exist would be if there were an equivalent excess of cost over productive expenditure, which is to say, if there were an equivalent negative net investment. But continuing negative net investment is an impossibility, if for no other reason than the exhaustion of assets.³⁴ In the absence of negative net investment, the existence of net consumption guarantees a corresponding positive average rate of profit.

There is a second aspect to the criticism that consumption should not be placed before income. This aspect concerns the genesis of what the businessmen and capitalists consume. I have said that businessmen and capitalists possess not only their incomes, but, first and foremost, their capitals. How, it will be asked, did their capitals originate, if not out of saving out of income? Here we are also involved in the question of how profit is the original form of income in the economic system.

To answer these questions, it must be realized that neither the portion of their exchangeable wealth which they devote to provision for the future nor the portion which they consume, need be acquired by businessmen and capitalists in the form of income—though, of course, in a developed market economy, they almost always will be. Incomes are generated in the process of exchange, and prior to every exchange there must be that which is to be exchanged. It is not income which is the necessary prerequisite to consumption, *but a fund of money*. This money can be acquired in the form of income, or it can be acquired by the printing or mining of new money, or by the emergence of a monetary employment for commodities already in one's possession which were acquired either by one's own labor or in barter exchange. The last two of these—that is, the mining of new money and the emergence of a monetary employment for commodities acquired either by one's own labor or in barter exchange—were the original source of consumption expenditure and of net consumption. The first incomes were generated by the spending of money, and the money which was spent could not have been acquired as income but only as a commodity produced by one's own labor or obtained in barter exchange.³⁵ Such is the original source of consumption expenditure and net consumption in the "early and rude state of society" described by Adam Smith, in which there is only a demand for consumers' goods and no demand for means of producing products which are to be sold.³⁶

Thus, true enough, the capitals of businessmen and capitalists are accumulated by saving out of profits. But profits themselves are always caused at least in part by net consumption, whether that net consumption is based mainly on previously accumulated capital, as in the

conditions of any modern economic system, or on the original sources I have just described. The essential point is that irrespective of the contribution of prior, saved profits to current and future net consumption, it is current and future net consumption that operate to determine current and future profits. Furthermore, the regress is not infinite, in that net consumption does have ultimate priority over profit in the way I have just shown.

An Explanation of High Saving Rates Out of High Incomes

We have considered the case of the effect of a loss of income on the consumption of businessmen and capitalists, and have seen that their consumption would not be diminished to anywhere near the extent to which their income falls, because it is based mainly on their possession of capital. Their consumption would tend to fall only to the relatively modest extent that the reduction in their income constituted a fall in the much larger total of their exchangeable wealth consisting of the sum of their capital plus their income as it is obtained. The same analysis applied to the case of the effect of a rise in income on the consumption of businessmen and capitalists shows that an increase in income will likewise tend to have only a modest effect. The increase in income will also tend to be consumed and saved in proportion as they employ this total of capital-plus-its-income in consumption and for making provision for the future.

For example, if the income of our hypothetical businessman or capitalist with \$10,000,000 of capital rose from \$500,000 to \$1,000,000, his consumption would most likely rise only to something on the order of \$525,000, while his provision for the future rose to something on the order of \$10,475,000, for these sums stand in approximately the same respective proportions to \$11,000,000 as do \$500,000 and \$10,000,000 to \$10,500,000. Thus he would consume only about \$25,000 of his additional income, and save all the rest of it. The percentage of his income that he saved would go from zero to almost 48 percent. In the same way, if the income he earned on his ten million of capital were \$1,500,000, his consumption would rise to something on the order of \$550,000 while his provision for the future rose to something on the order of \$10,950,000. At this point, the percentage of his income that he saved would be over 60 percent.

This analysis helps to explain both why individuals with higher incomes tend to save larger fractions of their incomes than do those with lower incomes and, at the same time, why there is no tendency toward an ever rising proportion of saving out of income in the economic system as a whole, as the average level of real income rises. It is not the case that individuals having higher incomes save a larger portion of them than individuals

having lower incomes, on the basis of any economic law pertaining to the absolute size of income. Rather it is the case that individuals with higher incomes are to a large extent businessmen or capitalists who earn a rate of profit that is higher than the rate of net consumption.

To the extent that this is the case, the income that is over and above what corresponds to the net-consumption rate counts merely as additional exchangeable wealth that is divided between consumption and provision for the future in essentially the same proportions as a lesser sum of exchangeable wealth consisting of capital plus its income. But this means that in the average case the only portion of the additional income that is consumed is a portion itself corresponding to the net-consumption rate, while all the rest goes to saving and provision for the future.

If these individuals were to earn the same amount of profit, however high that might be in absolute terms, and, at the same time, possessed a sufficiently larger amount of accumulated capital, they would consume the full amount of their high incomes. Let their accumulated capitals grow sufficiently relative to their incomes—in other words, let the rate of profit they earn fall to the net-consumption rate—and they will consume all of their income, however high it might be. For example, a businessman or capitalist with an income of \$1,000,000 a year may well save half or more of it when his total accumulated capital is \$10,000,000, but he would most likely consume all of a \$1,000,000 income—and more—if his accumulated capital were \$50,000,000, and most certainly if it were \$100,000,000. In such a case, his saving out of income would be zero or less than zero. Indeed, on our present assumptions, he would consume all of a \$1,000,000 income if his accumulated capital were just \$20,000,000.

The fact that high rates of saving are to be found in connection with high rates of profit can also be explained on the basis of the fact that a high rate of saving out of a high rate of profit is the basis of building a fortune. Repeated compounding of the high rate of profit on a rapidly growing capital sum, whose rapid growth is made possible by a high rate of saving, results in the accumulation of a fortune. A high rate of profit provides both the incentive and the means for a high rate of saving, culminating in the possession of a fortune.³⁷

As previously noted, apart from the connections between high rates of profit and high rates of saving out of income, Milton Friedman has shown the vital role played by expectations concerning permanent or long-run average income in leading individuals to save heavily in periods when their income temporarily exceeds their expectations of this kind. Thus, individuals such as best-selling novelists, prominent athletes, and movie stars,

whose incomes in an individual year or limited period of years are among the highest in the economic system, often save heavily. The reason they do so is not because their incomes are high absolutely or relative to those of the average member of the economic system, but because their incomes are high relative to their own expected long-run average incomes and thus need to be saved heavily to make possible a more even level of consumption over time.³⁸

Friedman's insight helps to explain high saving out of profits in a context in which the high rate of profit cannot be expected to continue. In this case, the profits must be heavily saved if the individual is to benefit from them in the years when his profit income will be lower, owing to the prospective fall in the rate of profit he will earn.

Friedman's insight can also be applied to understanding the disposition of previously accumulated capital between provision for the future and present consumption. Such capital will typically be regarded by its owner as having to serve his wants over a more or less extended period of the future. If the owner of a capital of \$10,000,000, wishes to provide for his wants over a period of twenty years, say, and to do so evenly, then the most he will wish to consume in the present year is \$500,000. If he earns no income this year, then his capital falls by that amount. In succeeding years, if he continues to earn no income, he may go on consuming \$500,000 a year until his capital runs out, or if his "time horizon," so to speak, remains constant at twenty years, he will progressively diminish his consumption as his capital declines, keeping it at a constant one-twentieth of the declining amount.³⁹

The present discussion makes it clear that the high rates of saving that take place out of the high incomes existing at any given time are not the result of the absolute height of those incomes. They are the result of the height of those incomes *relative* to accumulated capital or to the expected long-run average income of the individuals. Where high incomes are not earned as a high rate of profit on capital and are not perceived as higher than one's long-run average income, they are not accompanied by high rates of saving. That is to say, where they are earned in the form of a low rate of profit on a large sum of capital or where they are earned in the form of high wages which are expected to continue to be earned over the rest of one's life, the high incomes are not accompanied by high rates of saving. The businessman or capitalist with a large amount of capital relative to his income need not save, because he can look to his existing capital to provide for his future wants even if he consumes an amount equal to the whole or even somewhat more than the whole of his modest rate of profit. A wage earner who can expect to earn a high wage income

throughout his life can look to his future wages as the means of providing for his future consumption. It is not necessary for him to make provision for the future beyond providing for old age and other possible periods of incapacity, and for the purchase of goods that are too expensive to be purchased out of current income.

When these facts are understood, it becomes possible to explain such things as why the average American of today does not save a larger proportion of his income than did his grandparents, even though in real terms as well as in monetary terms his income is far greater than theirs was. As has just been shown, the explanation is that higher real income as such, that is, by itself, does not cause a higher rate of saving. Indeed, owing to changes in political conditions that affect the general security of property, such as the tax system and the monetary system, and to changes in cultural values that are philosophical corollaries of the political changes, today's generation of Americans saves *less* relative to its income than was the case in the past, even though, for the time being at least, real incomes continue to be far higher than in the past. Confiscatory taxation, fiat money and inflation, and the decline of the sense of individual responsibility have all worked to reduce the degree of provision for the future relative to current consumption and thus to reduce saving out of income, despite the fact that real incomes continue at a level far higher than prevailed in the past and, at least until relatively recently, had even continued to rise. The slower rate of increase in real income that is the result of these causes is also a major cause of the reduced rate of saving out of income. This is implicit in the preceding discussion.⁴⁰

Indeed, to maintain that individuals with higher incomes by that very fact tend to save relatively more than individuals with lower incomes, is to reverse cause and effect. This is because it is not high income as such which is the cause of high saving, but high saving which is the cause of high income, both absolutely and relatively. This point can be clearly seen in the light of the analysis we have been carrying on under the assumption of an invariable money. In this analysis, high saving and the high relative demand for capital goods that it makes possible is the cause of high and rising real income in that it is a leading cause of capital accumulation, rising production, and falling prices, which progressively increase the buying power of given money incomes. At the same time, those businessmen and capitalists who save relatively more grow in relative wealth and increase their profits at the expense of those businessmen and capitalists who save relatively less. These businessmen and capitalists have the highest and most rapidly rising real incomes, and while the monetary income of the average member of the economic system remains the same, theirs goes on rising.

The same point is dramatically confirmed by the rapid economic progress and consequent rise in real incomes of such East Asian countries as Japan, Taiwan, and South Korea. All of these countries, not so very long ago, were among the world's most impoverished nations. Their progress has its foundation largely in a very high degree of saving and provision for the future, which came into being in the midst of poverty. Their saving and provision for the future is clearly the cause, not the effect, of their high and rising real incomes.

Net Consumption and Time Preference

Net consumption is not an ultimate cause of profit. It itself reflects the operation of time preference. As explained in Chapter 2, time preference refers to the fact that, other things being equal, people value the satisfaction of their wants in the present more highly than in the future, and in the nearer future more highly than in the more remote future.⁴¹ Time preference determines the proportions in which people devote their income and wealth to present consumption versus provision for the future. The higher the prevailing degree of time preference, the higher is the proportion in which people devote their wealth and income to present consumption in comparison with provision for the future. The lower is the prevailing degree of time preference, the lower is the proportion in which they devote their wealth and income to present consumption in comparison with provision for the future. In this way, time preference operates to establish the rate of net consumption.

This is so, because to the degree that time preference is high, and people are therefore not prepared to make provision for the future relative to present consumption, the demand for factors of production to produce products which are to be sold will be low, the amount of capital invested will be low, and net consumption will be correspondingly high. Thus the ratio which net consumption and, therefore, profit bear to the demand for factors of production, to costs (which reflect that demand), and to the sum of the capital values of business enterprises will be high. By the same token, to the degree that time preference is low, exactly the reverse will be true and the rate of net consumption and the rate of profit will be correspondingly low. Thus, one can say that the ultimate cause and determinant of the rate of profit, insofar as it depends on net consumption, is time preference.

It may be asked, what is the temporal extent of the periods called the present and the future, between which individuals divide their wealth and income? The answer is that as far as the net-consumption theory is concerned, the absolute extent of these periods is of no importance. One may consider as the present, today, the coming

week, the coming month, the coming year, or any period of time extending into the future, however long or short. The reason is that every rate of profit or interest varies directly with the period of time taken as the base. For example, a 10 percent rate of profit on an annual basis is identical with a 20 percent rate of profit on a biennial basis, a 5 percent rate of profit on a semi-annual basis, a 2.5 percent rate of profit on a quarterly basis, and a five-sixths of 1 percent rate of profit on a monthly basis. And in precisely the same way that the ratio which the amount of profit or interest bears to a principal varies directly with the period of time under consideration, the ratio which net consumption bears to the sum of the capital values of business enterprises varies directly with the period of time under consideration. The ratio which the net consumption of two years bears to the sum of the capital values of business enterprises is twice as great as the ratio afforded by the net consumption of one year; this in turn is twice as great as the ratio afforded by the net consumption of six months, which, in turn, is twice as great as the ratio afforded by the net consumption of three months, and so on. Thus, if net consumption relative to the sum of the capital values of business enterprises proceeds at the rate of .0274 percent per day, .83 percent per month, 2.5 percent per quarter, 5 percent every six months, 10 percent per year, or 20 percent every two years, it is all the same. A rate of profit of 10 percent on an annual basis will be the result. The rate of net consumption and the rate of profit and interest are of the identical mathematical nature.

This explains, incidentally, why nothing essential depended on our simplifying assumption, earlier in this section, that the entire annual income on a capital sum was available on the first day of the year. It is immaterial whether one has a \$500,000 annual income available at the beginning of a year and consumes one's exchangeable wealth at the annual rate of one twenty-first, or has available, say, only a quarterly income of \$125,000 at the beginning of a quarter and consumes one's exchangeable wealth at the quarterly rate of one eighty-fourth.

It must be stressed that the connection between the rate of profit and time preference is not direct, but indirect. It exists insofar as time preference determines the proportions in which individuals devote their wealth and income to provision for the future relative to present consumption, as manifested in the proportion in which net consumption stands to the demand for factors of production to produce products which are to be sold and to the sum of the capital values of business enterprises. It does not operate on the rate of profit in any other, more direct way.⁴²

Perhaps the simplest way to understand the operation

of time preference on the rate of profit is in terms of the concept of the “time horizon” referred to previously.⁴³ If time preference leads businessmen and capitalists to have an average time horizon of twenty-one years, over which they wish to make even provision for their wants, then the rate of net consumption will be one twenty-first of capital-plus-its-annual-income. Since the amount of net consumption tends to generate an equivalent amount of profit, this will operate to make the annual income on capital also equal to one twenty-first of the sum of capital-plus-its-annual-income. Thus the rate of profit relative to capital alone will tend to be 5 percent.⁴⁴

In exactly the same way, if the average time horizon of businessmen and capitalists were eleven years, and thus they wished to consume an amount equal to one-eleventh of the sum of their capital and its annual income, the rate of net consumption and the rate of profit—as far as it depends on the rate of net consumption—would be 10 percent. If their average time horizon were 51 years, the rate of net consumption and the rate of profit—again, as far as it depends on the rate of net consumption—would be 2 percent.⁴⁵

The fact, explained in Chapter 2, that time preference in turn is itself profoundly influenced by the degree of rationality and freedom that prevails in a society implies that as far as the rate of profit depends on the rate of net consumption, it will be the lower, the more rational and the freer a society is.⁴⁶ Special emphasis must be placed on the implication that the rate of profit will be the lower the greater is the respect for property rights and thus the security of property. This is the case because to the degree that property rights are respected and property is secure, the more are people motivated to make provision for the future relative to present consumption, and thus the lower will be the rate of net consumption and the rate of profit insofar as the rate of profit depends on the rate of net consumption. In addition, the greater is the security of property, the more will people be motivated, with any given degree of time preference, to make provision for the future in the form of the accumulation of capital rather than the accumulation of hoards of precious metals and gems. This change in the form of provision for the future, given the same degree of time preference, also serves to lower the rate of net consumption and the rate of profit. This is because it represents a greater demand for factors of production by business and the accumulation of greater sums of capital value, as opposed to the accumulation of wealth in the form of consumer assets.

It is important to realize that, however ironically, it follows from these considerations, that all the demagogues and outright bandits in the world who rail against the height of profits and who call for or actually undertake the looting and plundering of property thereby labor

to raise the rate of net consumption as high as they can and thus correspondingly to raise the rate of profit. For in striving, as they do, to undermine the security of property in their various capacities of ordinary robbers, members of guerrilla bands, or officials of virtually all contemporary governments, they act to discourage saving and productive expenditure and thereby to increase the relative significance of net consumption. The message they send to businessmen and capitalists is: “Don’t save, don’t invest—because if you do, we will see to it that you do not benefit from doing so, for we will steal or destroy your property or tax it away. If you want to benefit from your wealth, you had better consume it before you lose it to us.”

4. Net Investment as a Determinant of Aggregate Profit and the Average Rate of Profit

The equality between profits and net consumption rests on an equality between productive expenditure and the costs deducted from sales revenues in business income statements. In such circumstances, an excess of sales revenues over costs is possible only to the extent that there is an excess of sales revenues over productive expenditure. As we have seen, since both sales revenues and productive expenditure embrace the demand for capital goods, an excess of sales revenues over productive expenditure rests on an excess of receipts from the sale of consumers’ goods over the demand for labor by business, that is, on net consumption. As we know, net consumption in turn is the result of the consumption expenditure of businessmen and capitalists, financed out of dividend, draw, and interest payments.

However, productive expenditure and costs need not be equal. For reasons I will explain, productive expenditure is usually greater than costs, and sometimes it is less. In these circumstances, net investment, positive or negative, exists. And at such times, the amount of profit in the economic system turns out to equal the sum of net consumption plus net investment.

Figures 16–1 and 16–2 and Tables 16–3 and 16–4 exemplify the fundamental distinction that exists between productive expenditure and costs. In these figures and tables, the productive expenditure of any given year shows up as costs deducted from sales revenues in the following year. By the same token, the costs of any given year are shown as representing the productive expenditure of the year before. Such a fundamental distinction of timing, whether of years, months, or weeks, usually exists between productive expenditure and the costs it generates in business income statements. In essence, today’s productive expenditures for the most part show up as costs in the future, while today’s costs for the most

Table 16-5
The Emergence of Net Investment

Year	Productive Expenditure	Costs	Sales Revenues	Profit	Net Consumption
1	800	800	1,000	200	200
2	900	800	1,000	200	100
3	900	900	1,000	100	100
4	900	900	1,000	100	100
...
N	900	900	1,000	100	100

The table above shows that in *Year 2*, profit remains at 200 despite the fall in net consumption to 100 and resulting rise in productive expenditure to 900. The reason is that the rise in costs lags the rise in productive expenditure. Only from *Year 3* on, will costs also be 900. In *Year 2*, the 100 excess of productive expenditure over cost implies the existence of 100 of net investment.

part reflect productive expenditures made in the past.

The distinction between productive expenditure and costs was explained in detail in Chapter 15. There it was shown that all of productive expenditure which is for plant and equipment or inventory and work in progress, is added to asset accounts, while the corresponding items of cost, namely, depreciation and cost of goods sold, which reflect previous productive expenditures, are subtracted from those asset accounts. On this basis, the difference between productive expenditure and costs in the economic system was shown to constitute net investment, that is, the net change in the value of those asset accounts.⁴⁷

The continuous equality between productive expenditure and the costs deducted from sales revenues that is found in Figures 16-1 and 16-2 and in Tables 16-3 and 16-4 is the result of nothing more than the assumption that productive expenditure is the same year after year, reinforced by the further assumption that all productive expenditure shows up as costs precisely one year later. Under these assumptions, productive expenditure and costs show up as the same in amount year after year, to the end of time.

Nevertheless, if one looks at Table 16-5, one can observe an important break in the equality between productive expenditure and costs, and, at the same time, an

equivalent break in the equality between profits and net consumption. Specifically, one will observe in *Year 2* of Table 16-5 that productive expenditure exceeds costs by 100, and, at the same time, that profits exceed net consumption by 100. For in that year, while productive expenditure is 900, costs are only 800, and while net consumption is only 100, profits in the economic system are 200.

Table 16-5 is very similar to Table 16-3. Its only essential difference is that in *Year 2* it introduces a rise in productive expenditure from 800 to 900 monetary units, which is made possible by an equivalent fall in net consumption from 200 to 100 monetary units.⁴⁸ In all subsequent years, 900 and 100 monetary units remain the respective magnitudes of productive expenditure and net consumption. Total sales revenues, of course, continue at 1,000 monetary units throughout, inasmuch as 100 monetary units of additional demand for the products of business generated by productive expenditure take the place of the 100 monetary units of reduced demand for the products of business coming from the consumption of businessmen and capitalists, viz., from net consumption.⁴⁹ What Table 16-5 shows is that even though productive expenditure in *Year 2* rises from 800 to 900, costs continue to be 800, reflecting the fact that productive expenditure in *Year 1* was 800. Only from *Year 3* on do

costs rise to the higher level of productive expenditure.

Because of this lag in the rise in costs to reflect the rise in productive expenditure, profits in *Year 2* continue to equal 200, despite the fall in net consumption to 100. This is the case inasmuch as sales revenues remain at 1,000 while costs remain at 800. All that has happened so far in Table 16-5 is that net consumption—the demand for consumers' goods by businessmen and capitalists—is down and productive expenditure and the demand for capital goods and/or the demand for producers' labor and producers' labor's demand for consumers' goods are up by just as much. Thus, there is no change in aggregate sales revenues and, as yet, no change in aggregate costs. As a result, profits are as yet unchanged, despite the fall in net consumption.

The unmistakable and obvious implication of this inequality between profits and net consumption is that something else, besides net consumption, determines the amount of profit in the economic system. That something else, of course, turns out to be nothing other than net investment. This is because the excess of profits over net consumption is the excess of productive expenditure over costs. Profits remain the same rather than fall to an amount equal to the smaller amount of net consumption, because, while sales revenues remain the same, costs have not yet risen to equal the larger amount of productive expenditure that the smaller amount of net consumption makes possible. If costs did equal the larger productive expenditure, profits would equal sales revenues minus the larger productive expenditure, that is, they would equal the smaller net consumption. So long as costs fall short of the larger productive expenditure, profits exceed the smaller net consumption. This shortfall of costs relative to productive expenditure, or, equivalently, this excess of productive expenditure over costs, is, as we know, net investment. For productive expenditure comprises debits or pluses to the assets of business, while costs comprise credits or minuses to those assets. Thus, to the extent that productive expenditure exceeds costs, the pluses to the assets of business exceed the minuses from those assets, with the result that there is an equivalent net change in the book value of those assets—viz., there is equivalent net investment.

In connection with this last point, it is necessary to keep in mind specifically that productive expenditure incorporates business spending on account of plant and equipment and inventory and work in progress, which represents debits or pluses to these respective asset accounts, while costs include depreciation and cost of goods sold, which represent credits or minuses to these respective asset accounts. The difference is net investment in plant and equipment plus net investment in inventory and work in progress. Insofar as productive

expenditure and costs do not comprise such pluses or minuses to assets, they represent identically equal expensed expenditures, that is, items that are not debited to any asset account, but written off—expensed—as made. Such items—for example, many advertising and research and development outlays—are simultaneously productive expenditures and costs. The subtraction of such costs from such productive expenditures nets to zero and thus leaves undisturbed the fact that total productive expenditure minus total costs equals net investment.⁵⁰

The relationship between profits and net investment is actually very simple. Net investment is productive expenditure minus costs. Profit is sales revenues minus those same costs. The great bulk of sales revenues, moreover, is generated by and is equal to productive expenditure. Productive expenditure, recall, embraces the demand for capital goods, which at the same time literally *is* a major component of sales revenues. Furthermore, productive expenditure embraces all the wage payments by business firms, which is the source of the far greater part of receipts from the sale of consumers' goods by business. Thus, to the extent that productive expenditure exceeds costs and produces corresponding net investment, the sales revenues generated by and equal to productive expenditure exceed those same costs and thus result in profits equal to the net investment. Once again, the existence of net investment means that productive expenditure exceeds costs. At the same time, it means that the portion of business sales revenues generated by and equal to productive expenditure exceeds those same costs, and thus that profit exists at least to the same extent as net investment exists. Indeed, the only thing that prevents a perfect identity between profits and net investment is the extent to which sales revenues exceed productive expenditure, that is, the extent to which net consumption exists.

Table 16-6 illustrates the effect of net investment on profits by incorporating the data from *Year 2* of Table 16-5 into a framework similar to that of Table 16-2, which set forth the role of net consumption in making possible an excess of the demand for the products of business over the demand for factors of production by business, that is, of sales revenues over productive expenditure. The table shows that aggregate profit in the economic system equals the sum of net investment plus net consumption. It does so by showing once again the demand for factors of production by business (productive expenditure) on the left and the demand for the products of business (sales revenues) on the right. It shows total sales revenues generated equal to the sum of productive expenditure plus net consumption: specifically, sales revenues of 900 generated by productive expenditure and sales revenues of 100 generated by net consumption.

Table 16–6
Net Investment as a Source of Aggregate Profit

Demand for Factors of Production by Business (Productive Expenditure)		≡	Demand for Products of Business (Sales Revenues)	
Demand for Capital Goods:	600	≡	Receipts from the Sale of Capital Goods:	600
Demand for Labor:	300	=	Receipts from the Sale of Consumers' Goods to Wage Earners:	300
Total Demand for Factors of Production by Business (Productive Expenditure):	900		Total Sales Revenues Generated by Productive Expenditure:	900
<i>less:</i>			<i>less:</i>	
Costs:	800	=	Costs:	800
Net Investment:	100		Profits Corresponding to Net investment:	100
			Receipts from the Sale of Consumers' Goods to Businessmen and Capitalists (Net Consumption):	100
			Total Sales Revenues:	1,000
			<i>less:</i>	
			Costs:	800
			Total Profits:	200
			Profits Corresponding to Net Consumption:	100

The 900 of sales revenues generated by productive expenditure are 600 of receipts from the sale of capital goods plus 300 of receipts from the sale of consumers' goods to wage earners. The 600 of receipts from the sale of capital goods, of course, are identically equal to the component of productive expenditure representing the demand for capital goods. The 300 of receipts from the sale of consumers' goods to wage earners are quantitatively equal to the component of productive expenditure representing the demand for labor. The 100 of sales receipts generated by the sale of consumers' goods to businessmen and capitalists are the receipts representing net consumption. Total sales revenues in Table 16–6, of course, equal 1,000, with 600 representing demand for capital goods and 400 the total demand for consumers' goods coming both from businessmen and capitalists and from wage earners, together.

Now the deduction of 800 of costs from 900 of pro-

ductive expenditure on the left-hand side of Table 16–6 results in net investment of 100. When those same costs are deducted on the right-hand side of Table 16–6 from the 900 of sales revenues generated by the 900 of productive expenditure, the result is 100 of profits corresponding to the 100 of net investment. Total profits, of course, are 200, rather than 100, because total sales revenues are 1,000, not 900. Sales revenues are generated by the sum of productive expenditure plus net consumption, not by productive expenditure alone. When the 800 of costs are deducted from this larger total of sales revenues, the total amount of profit surpasses net investment by the amount by which total sales revenues surpass the portion of sales revenues generated by productive expenditure alone, that is, by the amount of sales revenues generated by net consumption.

Perhaps the simplest way to think of the equality between profits and the sum of net consumption plus net

investment is in terms of the following relationships:

- (1) profits = sales – costs.
- (2) profits = sales – productive expenditure + productive expenditure – costs.
- (3) sales – productive expenditure = net consumption.
- (4) productive expenditure – costs = net investment.

Thus, substituting equations (3) and (4) into equation (2) we obtain:

- (5) profits = net consumption + net investment.

In other words, profits are sales minus costs. They are also sales minus productive expenditure plus productive expenditure minus costs. Inasmuch as both sales revenues and productive expenditure contain the demand for capital goods, sales revenues minus productive expenditure reduces to the demand for consumers' goods minus the demand for labor, that is, to net consumption. Inasmuch as productive expenditure represents pluses to assets, while costs represent minuses to assets, productive expenditure minus costs is net investment. Thus, profits equal net consumption plus net investment.

Table 16–7 further illustrates the relationship between net investment and aggregate profit by showing a variety of possible cost values and the corresponding effects on net investment and profits together. The table assumes that productive expenditure is constant at 800 and that net consumption is constant at 200, with the result that sales revenues in the economic system are constant at 1,000. For purposes of illustration, three different values for aggregate costs are assumed: 800, 700, and 900, labeled (1), (2), and (3) respectively. Under these assumptions, when costs are 800, that is, equal to productive expenditure and to the sales revenues generated by productive expenditure, both net investment and the profits corresponding to net investment are zero. Thus, total profits equal 200, which is the amount by which sales revenues exceed productive expenditure and the costs equivalent to productive expenditure. That is, in this case, profits equal net consumption alone. All of these results are indicated by the label (1). When costs are 700 in the face of the 800 of productive expenditure and the 800 of sales revenues generated by productive expenditure, net investment is 100 and the profits corresponding to net investment are 100. Thus, in this case, total profits equal 300—the sum of the 200 of net consumption plus the 100 of net investment. In other words, they are now equal to the sum of the amount by which sales revenues exceed productive expenditure plus the amount by which productive expenditure exceeds costs. These results are indicated by the label (2). When costs

are 900, net investment is minus 100 and profits altogether are 100, equal to the sum of the 200 of net consumption plus the minus 100 of net investment. In this case, profit is equal to the sum of the excess of sales revenues over productive expenditure less the excess of costs over productive expenditure. These results are indicated by the label (3).

As we have seen, the variation of profits with net investment is produced by the fact that net investment exists to the degree that productive expenditure is greater than costs. But since productive expenditure is directly or indirectly the source of equivalent sales revenues, any excess of productive expenditure over costs is accompanied by a precisely equivalent excess of sales revenues over those same costs, which excess represents precisely equivalent profits. That is, to whatever extent productive expenditure exceeds costs and generates net investment, the sales revenues generated by productive expenditure, and equal to productive expenditure, exceed those same costs and generate profit. Thus, to the extent that net investment is positive, and the portion of sales revenues generated by productive expenditure exceeds costs, the excess of total sales revenues over costs is equivalently enlarged and profits exceed net consumption by the amount of net investment. By the same token, to the extent that net investment is negative, and the portion of sales revenues generated by productive expenditure falls short of costs, the total of sales revenues exceeds costs by less than the amount of net consumption; that is, profits are reduced by the amount of negative net investment.

It may be helpful to think of matters this way: while net investment—the excess of productive expenditure over costs—represents an equivalent excess of the part of sales revenues generated by productive expenditure, and equal to productive expenditure, over those same costs, net consumption represents a further excess of sales revenues over costs—the excess of sales revenues over productive expenditure itself. By the same token, while net consumption would generate profits even if costs equalled productive expenditure, the existence of net investment means that costs are equivalently less than productive expenditure and equivalently less than the portion of sales revenues generated by and equal to productive expenditure, and thus that profits exceed net consumption by the amount of net investment.

Under the assumptions we have been making of an invariable money and that all the capital goods and labor of any given year are used up in producing the products just of the next year, net investment is necessarily of short duration. Under such conditions, it can exist only on the strength of a rise in productive expenditure founded on a fall in net consumption, and then it can last only for a

Table 16-7
The Relationship Between Profits and Net Investment

Demand for Factors of Production by Business (Productive Expenditure)			Demand for Products of Business (Sales Revenues)	
Demand for Capital Goods:	500	≡	Receipts from the Sale of Capital Goods:	500
Demand for Labor:	300	=	Receipts from the Sale of Consumers' Goods to Wage Earners:	300
Total Demand for Factors of Production by Business (Productive Expenditure):	800		Total Sales Revenues Generated by Productive Expenditure:	800
<i>less:</i>			<i>less:</i>	
Costs (1):	800		Costs (1):	800
Costs (2):	700		Costs (2):	700
Costs (3):	900		Costs (3):	900
Net Investment (1):	0		Profits Corresponding to Net Investment (1):	0
Net Investment (2):	100		Profits Corresponding to Net Investment (2):	100
Net Investment (3):	-100		Profits Corresponding to Net Investment (3):	-100
			Receipts from the Sale of Consumers' Goods to Businessmen and Capitalists (Net Consumption):	200
			Total Sales Revenues:	1,000
			Total Profits (1):	200
			Total Profits (2):	300
			Total Profits (3):	100
			Profits Corresponding to Net Consumption (in all three cases):	200

single year, before costs rise to equal the higher level of productive expenditure. This is the situation in *Year 2* of Table 16–5. As we shall soon see, however, in the absence of these assumptions, in particular the assumption of an invariable money, net investment can exist not only as a long-standing, indeed, permanent source of aggregate profit, but also with no tendency toward diminution in its quantitative importance relative to that of net consumption.

Now it follows that since the aggregate amount of profit in the economic system is equal to the sum of net consumption plus net investment, that the average *rate* of profit in the economic system equals not only the previously described net-consumption rate, but *the sum of the net-consumption rate plus the net-investment rate*. This is merely to say, that in equalling the amount of net consumption plus the amount of net investment, all divided by the amount of capital invested, the average rate of profit equals the amount of net consumption separately divided by the amount of capital invested (the net-consumption rate) plus the amount of net investment separately divided by the amount of capital invested (the net-investment rate). This is on the elementary algebraic principle that $\frac{a+b}{c} = \frac{a}{c} + \frac{b}{c}$. In other words, the average rate of profit in the economic system can be expressed as equal to and determined by the rate of net consumption plus the rate of net investment. This formula is of great importance, and I will refer to it repeatedly in subsequent discussion.

Net Investment Versus Negative Net Consumption

Because of net investment, it would be possible for an aggregate profit to exist in the economic system even in the complete absence of net consumption—indeed, even in the face of negative net consumption.

Net consumption falls below the consumption of businessmen and capitalists to the degree that wage payments fail to be accompanied by equivalent consumption expenditures. At the crudest level of analysis, one might imagine a portion of wage payments simply being hoarded by the wage earners. To this extent, receipts from the sale of consumers' goods to wage earners would be less than wage payments, and the excess of total receipts from the sale of consumers' goods over wage payments would be correspondingly diminished. The excess of total sales revenues over total productive expenditure would, of course, also be equivalently reduced, inasmuch as it reflects merely the addition of the demand for capital goods both to the demand for consumers' goods and to the demand for labor. The addition of equals to both sides of a diminished inequality does not alter the diminution of the inequality.

More realistically than being hoarded, a portion of wage payments might be used to finance additional productive expenditures. One can imagine, for example, employee stock-purchase plans, under which a portion of wages is turned back to business firms and used by the firms for the purchase of additional capital goods (or even for the payment of wages to additional workers). The same results would follow to the extent that the savings of wage earners that were deposited in banks were used in making loans to business firms, which then expended the proceeds of the loans in these ways. If—for lack of a better description—such *secondary* productive expenditures should exceed the financing of wage earners' consumption by means of loans extended by business firms, then, to that extent, consumption on the part of wage earners as a group would be less than the payment of wages.

The implication of a fall in net consumption here can also be seen in the fact that each dollar of wage income paid by business that is used to make productive expenditures represents two dollars of productive expenditure for every one dollar of sales revenues. This is because there is first a dollar of productive expenditure in the payment of the wages, and then, to the extent that the wages themselves are used to finance productive expenditure, a second dollar of productive expenditure in the expenditure of the wages. There is only one dollar of sales revenue, however, which occurs when the wages are expended in the purchase of capital goods, or when the wage earners whose wages are paid by means of secondary productive expenditure, purchase consumers' goods.

In these cases, total sales revenues in the economic system would still be the same, but productive expenditure would be larger and net consumption, therefore, as the difference between sales revenues and productive expenditure, would be equivalently reduced. Looked at in more detail, to the extent that the wage earners' savings were used to buy capital goods, receipts from the sale of capital goods would replace receipts from the sale of consumers goods to wage earners. This fall in receipts from the sale of consumers' goods, in the face of the same wage payments, would represent diminished net consumption. To the extent that the wage earners' savings were used to employ additional producers' labor, whose wages, it may be assumed, were themselves fully consumed, the result would be that while receipts from the sale of consumers' goods stayed the same, the total wages paid by business would rise. Either way, net consumption would be reduced.

It could also be the case, of course, that the savings of wage earners that were turned back to business would make possible merely the continuation of the same amount

of productive expenditure in the next period instead of a larger amount of productive expenditure in the current period. In this case, the situation would resemble the case of hoarding on the part of the wage earners, in that sales revenues in the current period would be reduced by the amount of such saving, and thus the difference between sales revenues and productive expenditure—i.e., net consumption—would again be equivalently reduced. Unlike the case of hoarding, however, business would receive back the cash it had expended, though in the form of loans or receipts from the sale of securities rather than in the form of sales revenues.

If businessmen and capitalists themselves consumed little or nothing, say, 5 or 10 monetary units instead of 100 or 200 monetary units, and at the same time there were a significant excess of secondary productive expenditure over the granting of new and additional consumer

loans by business to wage earners—that is, if the net amount of secondary productive expenditure were significant—the excess of wage payments over the consumption of wage earners would mean the existence of negative net consumption. But even in such an unlikely case, a significant aggregate profit and average rate of profit could still exist in the economic system on the strength of net investment alone. This is illustrated in Tables 16–8 and 16–9.

Table 16–8 assumes that the consumption of businessmen and capitalists is zero and thus that productive expenditure is the only source of sales revenues. It further assumes that a portion of wage payments is simply hoarded. It shows that despite this, an aggregate profit can exist on the basis of net investment. Specifically, the table assumes that the demand for capital goods is 500, and that while the demand for labor is 300, the wage

Table 16–8				
Net Investment as the Basis for Aggregate Profit With Sales Revenues Less Than Productive Expenditure Because of Hoarding or Saving to Finance Loans and Securities Purchases				
Demand for Factors of Production by Business (Productive Expenditure)			Demand for Products of Business (Sales Revenues)	
Demand for Capital Goods:	500	≡	Receipts from the Sale of Capital Goods:	500
Demand for Labor:	300		Receipts from the Sale of Consumers' Goods to Wage Earners:	200
Total Demand for Factors of Production by Business (Productive Expenditure):			Total Sales Revenues Generated by Productive Expenditure:	
	800		Total Sales Revenues Generated by Net Consumption:	0
<i>less:</i>			<i>less:</i>	
Costs:	600	=	Costs:	600
Net Investment:			Total Profits:	
	200		Profits Corresponding to Net Investment:	100
			Profits Corresponding to Net Consumption:	-100
			(The -100 is the result of the assumption of zero of consumption expenditure by businessmen and capitalists plus 200 of demand for consumers' goods by wage earners minus their 300 of wages.)	

earners consume only 200, because they have chosen to hoard 100 of their wages. Thus, sales revenues in the economic system turn out to be only 700 (500 + 200), while productive expenditure is 800 (500 + 300). The underlying basis of this shortfall of sales revenues in comparison with productive expenditure, namely, that wage earners consume only 200, while their wages are 300, represents negative net consumption in the amount of 100—viz., 200 of consumption minus 300 of wages. Nevertheless, even with sales revenues less than productive expenditure, an aggregate profit exists in Table 16–8 by virtue of the costs deducted from sales revenues being further below productive expenditure than are sales revenues. With aggregate costs of 600, as the table assumes, there is an aggregate profit of 100 on the 700 of sales revenues. At the same time, the subtraction of these

aggregate costs from 800 of productive expenditure results in net investment of 200. Thus 200 of net investment offsets 100 of negative net consumption and results in an aggregate profit of 100.

The excess of productive expenditure over sales revenues described in Table 16–8 could continue virtually indefinitely if, instead of the current saving of the wage earners being hoarded, which is a case so unlikely that it actually deserves hardly any consideration, they were used in financing loans to business or in purchasing securities from business. In this way, business could repeat its current level of productive expenditure in the next period.

Table 16–9 arrives at an essentially similar result to that of Table 16–8 under the assumption that a portion of wages is used to finance secondary productive expendi-

Table 16–9				
Net Investment as the Basis for Aggregate Profit With Sales Revenues Less Than Productive Expenditure Because of Secondary Productive Expenditure				
Demand for Factors of Production by Business (Productive Expenditure)			Demand for Products of Business (Sales Revenues)

	+ 100			+ 100
Demand for Labor:	300		Receipts from the Sale of Consumers' Goods to Wage Earners:	200
Total Demand for Factors of Production by Business (Productive Expenditure):			Total Sales Revenues Generated by Productive Expenditure:	800
	900		Total Sales Revenues Generated by Net Consumption:	0
<i>less:</i>			<i>less:</i>	
Costs:	600	=	Costs:	600
Net Investment:			Total Profits:	200
	300		Profits Corresponding to Net Investment:	300
			Profits Corresponding to Net Consumption	-100
			(Again, the -100 is the result of the assumed zero of consumption expenditure by businessmen and capitalists plus 200 of demand for consumers' goods by wage earners minus their 300 of wages.)	

ture in the same accounting period. It shows the wage earners' saving of 100 of their incomes resulting in a secondary productive expenditure of 100, which is added to the original, primary productive expenditure of 800, thereby bringing total productive expenditure to 900. For the sake of simplicity, the secondary productive expenditure is assumed to be entirely in the form of an additional demand for capital goods. Thus, Table 16–9 shows a demand for capital goods of $500 + 100$ and identical receipts from the sale of capital goods of $500 + 100$. By the same token, while it shows 300 of demand for labor, it shows only 200 of receipts from the sale of consumers' goods to wage earners. Thus, while productive expenditure is 900 ($500 + 100 + 300$), sales revenues are only 800 ($500 + 100 + 200$). The reason for the disparity, it must be recalled, is that the use of wages to buy capital goods adds to productive expenditure, but does not add to sales revenues; the expenditure for the capital goods merely takes the place of expenditure for consumers' goods. Because wages themselves are part of productive expenditure, the use of wages to make further productive expenditures has the ability in an extreme case such as the present, to raise productive expenditure above sales revenues.

Thus, in this case, there is again a shortfall of sales revenues relative to productive expenditure in the amount of 100, which represents negative net consumption in the amount of 100 (viz., only 200 of consumption accompanying 300 of wages). But once again, an aggregate profit exists on the strength of net investment—viz., on the strength of costs being below productive expenditure to an extent sufficient to enable them to be below the sales revenues that are below productive expenditure. In Table 16–9, net investment in the amount of 300 is accompanied by profit in the amount of 200. The net investment reflects the fact that while productive expenditure is 900, costs are only 600. Profit is 200, because even though sales revenues are 100 less than productive expenditure, costs are 300 less, which means that costs are 200 less than sales revenues. Thus, in this case, 300 of net investment offsets 100 of negative net consumption and results in an aggregate profit of 200.⁵¹

It must be stressed that the possibility of negative net consumption is extremely remote to begin with, since most savings of wage earners are used to finance consumption expenditures, such as the purchase of homes or personal automobiles, and to the extent that they are not, are largely or entirely offset by loans to wage earners from business for such purposes. Thus, as a practical matter, as I have already said, it is reasonable to assume that virtually 100 percent of wages has a counterpart in consumption expenditure. Moreover, to the extent that savings are used to finance loans for consumption expen-

ditures, the payment of interest on such loans represents a source of return on savings over and above ordinary net consumption—a source that may be termed *secondary net consumption*.

This is the case because the use of wages to pay interest on consumer loans not only constitutes consumption expenditure from the perspective of those who pay the interest, and, at the same time, interest income from the perspective of those who receive the interest, but also does not diminish the demand for the products of business. This last is because the recipients of the interest are able to spend the proceeds in buying goods or services from business. Thus the demand for the products of business remains the same, while the total of consumption expenditure and the total of interest income in the economic system are increased.

For example, total wage payments in the economic system could be 300 monetary units, of which the wage earners consume 270 monetary units in buying consumers' goods from business and pay 30 monetary units in interest on consumers' loans. The recipients of the 30 in consumers' interest—who could well be wage earners themselves, insofar as they had saved, and their savings had been lent to consumers—could then expend that 30 in buying consumers' goods of their own from business. As a result, everything would be the same except that 30 more in consumers' interest had been paid. The situation would be analogous to the case of the wage earners using part of their wages to employ consumers' labor—or paying taxes to the government, which uses the proceeds to employ consumers' labor.

In those cases, the effect is to increase the overall demand for labor while leaving all other spending magnitudes the same.⁵² Here, the interest on consumer loans is not at the expense of the profits and interest earned on the capital invested in ordinary business firms, but stands as a further source of net consumption and thus of aggregate profit and interest in the economic system. In fact, insofar as it is equivalent to net income, the payment of such interest constitutes a direct addition to the amount of net consumption in the economic system. This is because it is both consumption and, not being wages, an addition to the amount of consumption in excess of wage payments.⁵³ (Of course, the rate of interest on consumer loans, like the rate of interest on loans to business firms, is governed by the rate of profit on capital invested in business. This is because investing in business or lending to business is typically an alternative for whoever lends to consumers. At the same time, if additional funds are required for loans to consumers, the sources will most likely be parties presently engaged in these activities.)

However, what is decisive is that even if negative net consumption were to exist, however unlikely that might

be, its existence would necessarily be strictly temporary and would be followed by the resumption of a significantly positive rate of net consumption. As the analysis of the next subsection will show, this is because net investment can be indefinitely prolonged. As net investment occurs, the amount of capital invested in the economic system increases. So too, of course, does the volume of accumulated savings, which is comprised both of capital, which is by far its main constituent in any modern economic system, and savings invested in the financing of loans to consumers. In the context of an economic system with an invariable money, in which the sales revenues of business have a fixed limit and all other spending magnitudes are also constrained by the fixity of the quantity of money, the increase in accumulated capital and savings is not only an absolute increase, but also an increase relative to consumption expenditure and incomes. In other words, it constitutes an increase in the degree both of capital intensiveness in the economic system and in provision for the future relative to provision for the present. As a result, its effect is to provide the basis for greater and greater consumption expenditure relative to income, which puts an end to all possibility of negative net consumption.⁵⁴

The Prolongation of Net Investment Under an Invariable Money

When the assumption is dropped that the capital goods and labor of any given year are used up entirely in producing the output available at the start of the next year, then it becomes possible to observe a number of ways in which net investment can be prolonged, and, indeed, prolonged virtually indefinitely. Understanding this fact makes it possible to understand how an aggregate profit and thus a positive average rate of profit can exist even in conditions in which net consumption might be zero or negative and, at the same time, why any such situation with respect to net consumption is strictly temporary.

First of all, insofar as a fall in net consumption brings about a rise in productive expenditure specifically for plant and equipment, which serves in producing the output of a number of future years, the higher level of productive expenditure will result in net investment over a corresponding period of years. This can be illustrated in terms of an individual company.

Thus imagine that a company spends \$1 million per year on machinery which lasts 20 years. Even if such machinery goes into service at the very beginning of the year in which it is bought, the cost incurred on account of its use in that one year will not remotely equal its purchase price. Most likely, only one-twentieth of the purchase price of the machinery will show up as a cost

in any one year of its 20-year life. This is the result implied by the most commonly used method of calculating depreciation—the method known as straight-line depreciation—which is to depreciate an asset evenly over its entire life. Even where methods of accelerated depreciation are employed, only a fraction of a machine's purchase price is deducted from sales revenues in any given year, a fraction which is always the smaller, the longer is the expected useful life of the machine.

If the method of straight-line depreciation is followed, then the annual cost on account of the use of the machinery will be only \$50,000. Only over a 20-year period will the purchase price of the machinery show up as an equivalent cost, because that is the period over which the machinery serves in production. It follows that if every year this company spends \$1 million for such machinery, then only after 20 years will its total *annual* depreciation cost come to match its million-dollar annual outlay for such machinery. It further follows that until that happens, the firm's annual expenditure of a million dollars for such machinery results in net investment, which means in this case that net investment will be present for twenty years on the strength of this given, higher level of productive expenditure.

To clearly grasp this fact, it may help to realize that in *Year 2* of the present example, the firm will have 2 batches of such machinery, each incurring an annual depreciation of \$50,000. In *Year 10*, it will have 10 batches of such machinery, creating a total current depreciation charge of \$500,000. Only in *Year 20*, and thereafter, will it have 20 batches of such machinery, creating a total current depreciation charge of \$1 million. Thus, only from *Year 20* on, will its annual depreciation cost on account of such machinery equal its million-dollar annual outlay to purchase such machinery. Until that time, the firm's productive expenditure for machinery exceeds its depreciation on existing machinery and it experiences corresponding net investment in plant and equipment.⁵⁵

Obviously, the same relationships as just described apply to the expenditure for assets of any life. For example, if every year a business expends funds for buildings that will be depreciated over a 50-year period, then it would take 50 years for total annual depreciation cost on account of such buildings to come to equal the firm's annual outlay for such buildings. Thus, for 50 years, a given additional expenditure for such assets would result in net investment. The relationships obviously apply to the economic system as a whole. If, in the economic system as a whole, there is, say, \$500 billion of annual expenditure for machinery and buildings with an average life of 25 years, then such expenditure must be repeated for 25 years before aggregate depreciation cost in the

economic system equals the annual outlay for machinery and buildings. Until that time, there is net investment.

Net investment, and the aggregate profit that accompanies it, can exist not only by virtue of a fall in net consumption and rise in productive expenditure, but even with no fall in net consumption and no rise in productive expenditure. It can exist *by virtue of a change in the disposition of a given aggregate amount of productive expenditure*. For example, to the extent that productive expenditure shifts from expensed expenditures to expenditure on account of inventories, the productive expenditures involved are debited to assets instead of being instantaneously deducted from sales revenues as costs. The expenditures are added to the inventory/work-in-progress account and thereby result in an equivalent diminution of the costs deducted from sales revenues. Thus, there is net investment and corresponding profit.

To the extent that productive expenditure that is already on account of inventories or work in progress is shifted to the account of inventories or work in progress of a kind that requires a longer period of time before coming to market, there is a correspondingly greater deferral of the time before the productive expenditures involved show up as costs deducted from sales revenues. To take an obvious example, if the whiskey distilleries shift from the production of eight-year-old scotch to the production of twelve-year-old scotch, twelve years must go by instead of eight before the outlays for raw whiskey become deductions from sales revenues.

The same kind of phenomenon is potentially present in every case in which products or methods of production entail different periods of time in going from the purchase of labor and materials to a product sold to buyers. In every such case, a shift to products or methods of production requiring more such time represents a correspondingly greater period during which current productive expenditures on account of inventory and work in progress exceed the costs currently being deducted from sales revenues as costs of goods sold.

To use the whiskey example, the shifting of a given amount of productive expenditure from the making of eight-year-old scotch to the making of twelve-year-old scotch, and maintaining this shift throughout the years, means that there will be four years during which the productive expenditures being made for the purpose of producing whiskey remain the same, and the sales revenues they directly or indirectly generate elsewhere in the economic system remain the same, but in which the costs deducted from sales revenues fall, because the assets in question remain in inventory or work in progress. In all such cases, there is less aggregate cost in the economic system and correspondingly more monetary value in the form of inventory/work in progress. In other words, there

is correspondingly more net investment and profit.

In this particular case, in which the whiskey industry is assumed to productively expend just the same amount each year, the reduction in aggregate costs would occur specifically in the whiskey industry, which would withhold some of its product from the market for four years. But it could also be the case, and would be far more likely to be the case, that the shift to the production of twelve-year-old scotch would be made possible by a shifting of productive expenditures from outside the whiskey industry to the whiskey industry, rather than by a shifting within the whiskey industry itself. Thus, for the first four years in which the greater concentration on the production of twelve-year-old scotch takes place, the outlays could be financed by funds coming from outside the whiskey industry. This would leave the whiskey industry free to go on producing eight-year-old scotch during that time. Only thereafter would less expenditure be made within the whiskey industry on behalf of producing eight-year-old scotch. Only at the start of *Year 5*, would the whiskey industry shift a portion of its own funds previously devoted to the acquisition of raw whiskey that would be laid up for eight years, to the acquisition of raw whiskey that would be laid up for twelve years. Its ability to supply whiskey eight years later would not be diminished because, thanks to the previous infusion of funds from the outside, it would already be in possession of a comparable quantity of four-year old whiskey rather than raw whiskey. In this way, eight years later, just as the eight-year-old scotch came to be in reduced supply, its place would be taken by a correspondingly greater supply of twelve-year-old scotch. In this, more likely case, the reduction in aggregate costs in the economic system takes place *outside the whiskey industry*—in all those industries from which productive expenditures of a kind fairly quickly showing up as costs are withdrawn in order to finance the production of twelve-year-old scotch.

A much greater effect on behalf of net investment, of course, results from the shifting of productive expenditures from expensed expenditures and for inventory and work in progress to expenditures for plant and equipment, and from plant and equipment of a shorter life to plant and equipment of a longer life. Still more powerful effects are achieved in cases in which productive expenditures are shifted to expenditures for plant and equipment which not only last a longer time, but require a greater period of time in their construction. Productive expenditures shifted to things like bridges, tunnels, and canals result in net investment going on for a period of years equal to the sum of the construction time plus the period of useful life over which such assets are depreciated. Only when a given amount of such productive expenditure is repeated for this long a time, does annual

depreciation cost come to equal such annual productive expenditure. Finally, the most enduring source of net investment of all would be productive expenditure for assets of a kind that normally do not depreciate, notably, urban land.⁵⁶

In every case in which productive expenditure in the economic system is shifted from a point closer to showing up as a cost deducted from sales revenues to a point further removed from showing up as a cost deducted from sales revenues, the effect, for some period of time, is to bring about a reduction in the aggregate costs deducted from sales revenues. This reduction when taken relative to productive expenditure constitutes net investment. This same reduction when taken relative to sales revenues, which themselves, of course, are generated for the most part by productive expenditure, constitutes an equivalent increase in aggregate profits. Always, the net investment and profit brought about by such shifting of productive expenditure last until a period of time has gone by that is sufficient for the temporally more remote annual productive expenditure to show up in equivalent annual cost.

Net Investment as the Result of the Marginal Productivity of Capital Exceeding the Rate of Profit

The cause of a shift in the disposition of a given amount of aggregate productive expenditure to points more remote from showing up as costs deducted from sales revenue, and the creation of net investment thereby, can be found in an excess of *the marginal productivity of capital* over the prevailing rate of profit. The marginal productivity of capital in this context must be understood in a special sense—namely, as the savings of cost or additions to sales revenue that additional capital would achieve for individual business firms, relative to the additional capital in question.⁵⁷ If, for example, the employment of an additional \$1,000,000 of capital would have the effect of reducing the annual costs incurred by a business firm in producing its present output by \$100,000, then the marginal productivity of capital for this firm would be 10 percent. The same marginal productivity of capital would be present if the employment of an additional \$1,000,000 of capital would make it possible for the firm to produce improved products at the same total annual cost as it now produces its present products, which improved products would bring in an additional \$100,000 in annual sales revenues to the firm. The marginal productivity of capital in general represents the array of the marginal productivities of capital of all the individual firms, arranged in descending order. It is the array of all firms' prospective cost reductions or revenue increases that they expect to be achievable in connection with their present volumes of output, relative to the

additional sums of capital that they perceive would be required to achieve them.

Insofar as the marginal productivity of capital is above the going rate of profit in the economic system, an incentive is created to withdraw capital from existing employments to employments of the kind requiring new and additional capital, that is, to more capital-intensive employments. This is because, comparatively speaking, such a change in the employment of capital appears as the more profitable use of the capital in the circumstances. More capital intensiveness is what offers the prospect of lower unit costs through greater efficiency and/or higher selling prices because of improved quality of products.

For example, in the grocery-store industry, those grocery stores with better warehouse facilities, better buildings and fixtures, and a wider variety of merchandise offer a prospect of reduced costs and greater sales revenues compared to grocery stores lacking these improvements. If the size of these cost savings and/or revenue increases relative to the additional capital required to achieve them is greater than the rate of return currently being earned in the grocery business and in the economy generally, then an incentive is created to move capital from its present, relatively less-capital intensive employments in the grocery business into such more-capital-intensive employments, because this is where the capital in question will be employed more profitably. To the extent that the same situation obtains in other industries, the same incentive will exist with respect to the movement of capital in and between them. Thus, if automobile or steel companies with more modern factories and machinery can achieve cost savings or revenue increases relative to the necessary additional capital that are greater than the rate of profit prevailing in those industries and in the economy generally, the incentive will also exist to move capital from its present, relatively less-capital intensive employments in those industries into such more-capital-intensive employments in those industries, because this is where the capital in question will be employed more profitably. (Mergers among existing firms can obviously be highly instrumental in achieving such greater capital intensiveness.)

Now in the face of a given aggregate amount of productive expenditure, the withdrawal of capital from existing employments, where the going rate of return is being earned, to more capital-intensive employments, which offer the prospect of a higher rate of return, entails the shifting of productive expenditure from points temporally less remote from the earning of sales revenues to points temporally more remote from the earning of sales revenues. This is inherent in the nature of movement toward greater capital intensiveness. This in turn oper-

ates to create net investment in the economic system and correspondingly to raise the amount and rate of profit in the economic system. It does so by virtue of the fact that the withdrawal of capital from existing, temporally less remote investments reduces the costs deducted from productive expenditure and sales revenues before the investment of capital in the temporally more remote investments raises such costs. In the interval, there is an addition to net investment and to aggregate profit in the economic system. To take a very simple and dramatic example, the elimination of a portion of the daily expenditures of several pushcart peddlers for groceries at wholesale and its replacement with an equivalent daily expenditure for the construction of grocery stores, means an equivalent virtually immediate reduction in costs deducted from sales revenues and the passage of many years before the appearance of equivalent costs in the form of depreciation on grocery stores.

As I have indicated, the transfer of capital from less remote to more remote employments occurs between industries as well as within industries. For example, it is obvious in such cases as the transfer of capital from investment in grocery stores, say, to investment in electric utilities, say. But the phenomenon is no less present in the provision of new and additional capital for grocery stores by means of the transfer of capital from the electric utility industry, insofar as the capital being transferred is capital invested in such things as inventories and meeting expensed expenditures, while what it is being transferred to is capital invested in fixtures and buildings.

An inference to be drawn from the preceding analysis is that the existence of a marginal productivity of capital in excess of the rate of profit leads to the formation of new and additional capital. This is implied in the fact that the shifting of capital and productive expenditure to more remote employments calls net investment into being. The net investment is an addition to capital.

Despite its role in the causation of net investment and thus profit, it cannot be stressed too strongly that the marginal productivity of capital never directly determines the average rate of profit in the economic system. The rate of profit is always directly determined by the rate of net consumption and the rate of net investment.

The marginal productivity of capital is a concept that properly pertains only to cost savings or revenue increases of individual firms that are achievable by means of the employment of additional capital. Moreover, such cost savings or revenue increases by themselves need not result in corresponding actual profits even for the individual firms that experience them, let alone for the firms with which these firms compete. To say that costs are reduced or revenues increased by \$100,000 by virtue of

the employment of an additional \$1,000,000 of capital is not a sufficient basis for assuming even that the firm employing the additional capital earns a 10 percent rate of profit on its capital. It could well be that all that is involved is that its losses are now \$100,000 less than before and its rate of loss is correspondingly reduced.

Furthermore, under an invariable money, to whatever extent lower costs or improved products on the part of this firm result in its having greater sales revenues, other firms in its industry or elsewhere in the economic system will have correspondingly lower sales revenues and thus lower profits. Clearly, there is no basis for making any direct inferences concerning the average rate of profit in the economic system on the basis of the marginal productivity of capital.⁵⁸

The impact of the marginal productivity of capital on the rate of profit in the economic system is always indirect, through its effect on the rate of net investment. When the marginal productivity of capital is above the rate of profit, net investment occurs and the rate of profit rises. On the other hand, when the marginal productivity of capital is below the rate of profit, capital is withdrawn from temporally more remote employments to make possible investment in temporally less remote employments, which, in affording the going rate of return, by comparison now appear to offer more profitable uses for the capital in question. In the process, net investment is reduced—indeed, it might even become negative—and the amount and rate of profit are reduced.⁵⁹

A leading implication of this discussion is that a tendency exists for the rate of profit and the marginal productivity of capital to equalize, in that when the marginal productivity of capital is above the rate of profit, additional net investment is induced and the rate of profit rises, and when the marginal productivity of capital is below the rate of profit, net investment is curtailed and the rate of profit is reduced.⁶⁰

Another important implication of this discussion is that the marginal productivity of capital—in the sense in which I employ the term—is not a matter merely of physical or technical factors. It depends no less on factors that are ultimately a matter of value judgments and psychology. For example, if the demand of the public shifts from a good such as eight-year-old scotch to a good such as twelve-year-old scotch, the marginal productivity of capital is correspondingly increased, inasmuch as by this action the public is now willing to allow a greater premium in the price of a product requiring a greater degree of capital intensiveness in its production. The principle, of course, applies to any shift in demand from goods produced under a lower degree of capital intensiveness to goods whose production requires a higher degree of capital intensiveness.

Net Investment as a Self-Limiting Phenomenon

The fact that net investment takes place in response to the marginal productivity of capital being above the rate of profit, combined with the further fact that net investment itself adds to the rate of profit in the form of the previously described net-investment rate, implies that net investment is an inherently self-limiting phenomenon. This is because the greater is net investment, the higher, other things being equal, is the rate of profit and thus the fewer are the cases in which the marginal productivity of capital exceeds the rate of profit, and thus the more improbable is any further increase in the net-investment rate.

This inherent self-limitation of the net-investment rate operates as an important safeguard against any possibility of even the short-run interests of wage earners being unduly denied for the sake of capital accumulation.⁶¹ This is because any undue increase in net investment would operate to raise the rate of profit relative to the marginal productivity of capital and thereby operate to discourage or even reverse the movement toward greater capital intensiveness. Thus, the extent to which the demand for labor might be reduced in order to make possible an increase in the demand for capital goods is always inherently limited.

Capital Intensification and the Tendency Toward the Disappearance of Net Investment Under an Invariable Money

As should already be clear from preceding discussion in this chapter, *a tendency exists for net investment to disappear under an invariable money*. However more remote that portions of productive expenditure may become from having to be deducted from sales revenues as costs, still, if any depreciation whatever exists in connection with such productive expenditures, their continuation year after year will eventually be accompanied by annual depreciation costs that are just as great as those productive expenditures. At that point, the net investment and profits connected with the shift to such productive expenditures come to an end.⁶² And if the more remote productive expenditures are not continued until this time, then the associated net investment and aggregate profit come to an end all the sooner, because the shifting of productive expenditures back to points temporarily less remote from being deducted as costs from sales revenues results in the rise in costs to a point of equality with productive expenditure all the sooner.

Under an invariable money and its concomitant limitation on the amount of productive expenditure, the only thing which can make possible the continuation of net investment is the *continual* shifting of productive expenditures to points temporally more remote from being

deducted as costs from sales revenues. Given the existence of such continual shifting, it is possible to imagine the existence of a given amount of net investment going on virtually indefinitely. Indeed, its continuation would be positively encouraged by the falling rate of profit that is implicit in the situation, and which would operate to keep the rate of profit below a falling marginal productivity of capital as the amount of accumulated capital increased.⁶³ A fall in the rate of profit in this case is implied insofar as the rate of profit depends on the rate of net investment. It follows from the fact that the same amount of net investment would have to be divided by an amount of capital that continually grew by virtue of the net investment. Thus the net investment rate would fall and the rate of profit would fall insofar as it was governed by the net investment rate.

However, because of the existence of net consumption and thus a positive rate of net consumption, the fall in the rate of profit proceeds more slowly than the fall in the rate of net investment. It falls toward the rate of net consumption and can fall no lower without *negative* net investment taking place, which is clearly not in question here. Thus the encouragement given to net investment by a falling rate of profit progressively diminishes and ultimately must cease altogether.

The existence of any given positive rate of profit in the economic system, based on the rate of net consumption or on a combination of the rate of net consumption and some positive rate of net investment, makes the continual shifting of productive expenditures to more remote points in relation to their deduction as costs from sales revenues progressively more difficult. This is because the existence of any given positive rate of profit requires that to the degree that returns on investment must be postponed, they must be greater at least to the extent of providing a return equal to the going rate of profit compounded for the longer period of time in question. Thus, for example, if the going rate of profit is 5 percent per year, then a productive expenditure made one year in advance of the corresponding sale, needs to bring about at least \$5 of profit; more precisely, it needs to bring about at least \$5 of additional profit or reduced losses, achieved by means either of reducing costs or adding to sales revenues in the amount of \$5. A productive expenditure made two years in advance of the corresponding sale, needs to bring in at least \$10.25 in one of these ways, and so on, with the required amount of return increasing at a 5 percent compound rate. Obviously, the higher is the rate of profit, the greater is the obstacle presented by compounding.⁶⁴

In the absence of a continual shifting of productive expenditures to points temporally more remote from their deduction as costs from sales revenues—which

ultimately becomes impossible by virtue of the requirement of achieving cost reductions or revenue increases equal at least to those imposed by the rate of net consumption compounded for the length of time in question—costs begin to rise toward productive expenditure. The result is a steady diminution in the amount of net investment and in the amount of corresponding profits in the economic system. The ultimate result is that in the conditions of an invariable money, *aggregate profit tends toward equality with net consumption alone.*

In effect, the existence of the combination of capital accumulation based on net investment, and a positive rate of profit based at least on the rate of net consumption, sooner or later serves to bring to an end the ability of the marginal productivity of capital to surpass the rate of profit and thereby to continue to call net investment into being. The ultimate result, once again, is that the rate of profit comes to be based on net consumption alone.

The tendency toward the disappearance of net investment under the conditions of an invariable money is greatly reinforced by the fact that an indirect consequence of net investment is an increase in the amount of net consumption in the economic system and thus a corresponding decrease in the amount of productive expenditure. Thus net investment tends to disappear by virtue both of a rise in costs toward the level of productive expenditure and, at the same time, a fall in the magnitude of productive expenditure itself.

Net investment results in a rise in net consumption and thus fall in productive expenditure because its existence constitutes an increase in the amount of accumulated capital and thus of accumulated savings in general. In an economic system with an invariable money, and in which, therefore, aggregate money income does not increase, the increase in the amount of accumulated capital and savings represents a rise in the *ratio* of accumulated capital and savings to income. As capital and savings accumulate relative to income, the need and desire of people to increase their accumulated capital and savings still further relative to their income diminishes, while their desire to consume their income correspondingly increases.

Thus, individuals with no accumulated capital or savings whatever, have an urgent need to save and accumulate capital. Those who have accumulated capital and savings equal to a year's income, say, have a less urgent need to do so. Those who have accumulated capital and savings equal to two, three, or five years' income have a still less urgent need to do so, and so on. At some sufficiently high ratio of accumulated capital and savings to income, the average member of the economic system feels no need to raise the ratio of his accumulated capital and savings any further. Thus, as the ratio of accumulated

capital and savings to income rises, net consumption rises and productive expenditure falls. Any possible diminution of net consumption stemming from saving out of wages diminishes, disappears altogether, and is followed by a positive contribution to net consumption on the part of wage earners, a contribution which joins with the growing consumption of businessmen and capitalists, as their accumulated capital and savings increase. The accumulation of savings in the form of loans for the purchase of consumer assets, such as homes and the land sites they occupy, also contributes to rising net consumption and thus to falling productive expenditure.⁶⁵

Because of the above reasons, under the conditions of an invariable money, net investment tends to disappear, thereby leaving net consumption as the sole determinant of the amount and rate of profit.

The Process of Capital Intensification

A related approach for understanding the process whereby net investment ultimately must disappear under an invariable money, is to observe just how the economic system becomes more capital intensive as the result of a process of saving. At the same time, this will provide further understanding of the fact that any possible negative net consumption that might temporarily exist as the result of saving on the part of wage earners, must also disappear.

This approach requires tracing out the process of capital intensification step by step. This is done in Table 16–10. In this table, the economic system is assumed to begin with an annual aggregate expenditure for consumers' goods of 500 units of money. The total value of the capital employed in this economic system at all stages of production combined is assumed initially to be 1,000 units of money. This sum is the value of all the land, buildings, fixtures, plant, and equipment of business firms, less accumulated depreciation reserves, plus the value of all the inventories and work in progress that business firms possess. It also includes the quantity of money held by business firms.⁶⁶ Please note that what is referred to here is the value of the capital *stock* of the economic system, not the annual expenditure for capital goods.

The ratio of accumulated capital to consumption, or, more precisely, to the sum of consumption plus net investment, is typically called the capital-output ratio. More correctly, of course, it should be called the capital-*net*-output ratio, inasmuch as consumption plus net investment represents the net product of the economic system, not the actual total output.⁶⁷ Because of the equality between net product and national income, the ratio can also be expressed as the ratio of capital to national income.⁶⁸ Its closeness to the ratio of capital to

KEY:

K is the value of the accumulated capital stock at year end.

C is the total expenditure for consumers' goods in the current year.

I is net investment in the current year.

$K/(C+I)$ is the ratio of total accumulated capital to current net national product.

C_1 is the demand for consumers' goods in the following year.

I_1 is the volume of net investment in the following year.

K_1 is the portion of existing accumulated capital employed in the production of consumers' goods to be sold in the following year.

K_2 is the portion of existing accumulated capital employed in the production of the portion of next year's NNP that is represented by net investment.

consumption makes it obvious that the so-called capital-output ratio can be taken as a measure of the degree of capital intensiveness in the economic system, alongside the ratios we have mainly used up to now, namely, the ratio of capital to consumption, wages, and sales revenues respectively.⁶⁹

What is necessary at this point is to trace out how saving brings about a rise in the capital-net-output ratio from its initial level to a higher level. For the sake of simplicity, the example describes how the ratio is raised from an initial level of 1,000/500 to 1,500/500, or from 2:1

to 3:1. It should go without saying, that the principles contained in this example are applicable to the process of capital intensification in general, that is, to a rise in the capital-net-output ratio from any given starting level to any other given level, and for any absolute values of consumption expenditure (or consumption expenditure plus net investment) and the capital stock.

The table assumes that the process of capital intensification is brought about by a reduction in consumption expenditure from 500 to 450 for a period of 10 years. It assumes that in each of these 10 years 50 of savings out

of net income are invested and added to the preexisting value of the accumulated capital stock, which means that 50 of net investment occurs in each year. It further assumes that once the value of the capital stock has been increased by a cumulative total of 500, so that the ratio of accumulated capital (savings) to income stands at 3:1, people are content with their degree of provision for the future and thus restore their consumption expenditure to 500.

The first column of the table is simply a series of years. The second column, K , presents the amount of accumulated capital year by year; the third, C , the amount of consumer spending year by year; and the fourth, I , the amount of net investment year by year. For the sake of simplicity, I follow my usual practice of assuming that all financial transactions take place on the first day of the year. In the present case, this permits dealing with the net investment of each year both as adding to the accumulated capital of that year and as contributing to the net output available at the start of the following year. Thus, for example, the accumulated capital of 1,050 shown for *Year 3* both incorporates the 50 of net investment made in *Year 3* and serves in the production of the net output that becomes available at the start of *Year 4*.

For each year, the fifth column of the table, $K/(C+I)$, presents the ratio of accumulated capital to the so-called net national product (NNP), which, of course, is equal to the sum of consumption plus net investment and to national income. Initially, NNP is equal to 500 of consumption expenditure alone, and will be once again, at the conclusion of the process. But in the interval, as the process of capital intensification takes place, NNP is equal to the sum of 450 of consumption plus 50 of net investment. Because the net product of the economic system comes to be divided into these two portions, 450 of consumption and 50 of net investment, the total accumulated capital stock of the economic system comes to be divided into two corresponding portions: the one portion serving in producing the part of the net product purchased by the consumers, the other portion serving in producing the part of the net product that constitutes net investment.

The division of the capital stock in this way is shown in the last two columns of the table, headed K_1/C_1 and K_2/I_1 . It should be observed that C_1 is the demand for consumers' goods of the following year, and, accordingly, K_1 is the portion of existing accumulated capital employed in the production of consumers' goods to be sold in the following year. By the same token, I_1 is the volume of net investment of the following year, and K_2 is the portion of existing accumulated capital employed in the production of the portion of next year's NNP that is represented by net investment. (This aspect of the table

is similar to Figures 16-1 and 16-2, in which the disposition of the factors of production within each year is assumed to conform to the pattern of the relative demands for consumers' goods and capital goods in the following year. The difference is that now the disposition of the net output in the following year between consumption and net investment is taken in place of the relative demands for consumers' goods and capital goods, which categories of goods, of course, are the components of gross output.⁷⁰)

In Table 16-10, *Year 1* represents an initial equilibrium. It shows how the economic system has been operating up to this point. The value of the capital stock is 1,000, the demand for consumers' goods is 500, and the capital-net-output ratio is 2:1.⁷¹ In *Year 2*, consumption spending continues to be 500 and saving and net investment continue to be zero. But in this year, the allocation of capital undergoes an important change, in anticipation of the drop in consumption of 50 and emergence of 50 of net investment that is to occur in *Year 3*, and which will be maintained for a total of 10 years, viz., through *Year 12*. Accordingly, in *Year 2*, 100 of capital is transferred from the production of consumers' goods for *Year 3* to the production of the part of the net output of *Year 3* that will be represented by net investment. Hence, in *Year 2*, K_1/C_1 is $900/450$ and K_2/I_1 is $100/50$. To describe matters in terms of concretes, what will happen in *Year 3* is that there will be 50 less of spending for such goods as residential housing and personal automobiles, and 50 more of spending for such goods as factory buildings, trucks, and freighters. Accordingly, in *Year 2*, 100 of capital is shifted from the production of such goods as residential housing and personal automobiles to the production of such goods as factory buildings, trucks, and freighters.

In *Year 3*, 50 of saving and net investment occur and result in a rise in the accumulated capital of the economic system from 1,000 to 1,050. This additional 50 of capital is divided between the production of consumers' goods for *Year 4* and the production of the portion of the net output of *Year 4* which is represented by net investment; that is, it is divided in the ratio of *Year 4*'s demand for consumers' goods to *Year 4*'s net investment, i.e., in the ratio of 450:50, or 9:1. Thus, 45 of the additional capital is devoted to the production of consumers' goods of *Year 4*, and 5 of the additional capital is devoted to the production of the part of the net output of *Year 4* that is represented by net investment. Observe that from this point on the employment of capital in the production of consumers' goods begins rising. Both the production of consumers' goods and the production of the goods represented by net investment become progressively more capital intensive.

The process of increasing capital intensiveness in the production both of consumers' goods and the portion of net output represented by net investment continues from *Year 3* to *Year 11*. By *Year 11*, total capital has risen from 1,000 to 1,450, of which 1,305 are employed in the production of consumers' goods for *Year 12*, and 145 in the production of the part of the net output of *Year 12* that will constitute net investment. In *Year 12*, however, the final 50 of additional capital is accumulated, and, at the same time, the allocation of capital is shifted back from the industries producing for net investment and the increase in capital intensiveness to the industries producing consumers' goods. This is because having achieved the desired higher ratio of accumulated savings to current income by *Year 12*, people once again consume the whole of their nominal incomes starting in *Year 13*.

Of course, both the beginning and the end of the process need not be as abrupt as I have described it. There could be a gradual increase in saving and net investment accompanied by a gradual shift in the allocation of capital to the production of goods representing net investment. And the later, reverse movement could be equally gradual. Nor is it necessary that the changes in the consumption/saving pattern be anticipated with the precision I have presented. Any lack of anticipation of the initial shift will result in comparatively higher profits for the capital goods industries and comparatively lower profits for the consumers' goods industries, because to this extent there will be a greater demand relative to supply in the case of capital goods and a smaller demand relative to supply in the case of consumers' goods. By the same token, lack of anticipation of the later, reverse shift will result in comparatively higher profits for the consumers' goods industries and comparatively lower profits for the capital goods industries, because now the opposite imbalance would ensue.

Under all conditions, however, at the end of the process, the net effect is that people end up with greater provision for the future (both absolutely and relatively), production is more capital intensive, the supply of goods is more abundant and can go on increasing more rapidly (thanks to the increased ability to implement technological advances that more capital intensiveness makes possible), and people restore their consumption expenditure in a condition in which they are better able to afford to do so. It thus works out to be the same as for an individual, who first saves and, as a result, later on puts himself in the position of being able to afford to step up his consumption.

And in just this way, any saving on the part of wage earners which did have the effect of bringing about negative net consumption would prove temporary. It would go on only until wage earners had accumulated

savings sufficient to enable them to consume the whole of their wages, at which point, everyone in the economic system would be better off than he had been before. (To be sure, the wage earners would not only consume the whole of their wages but the whole of any profits or interest currently earned on the capital they had accumulated.)

It should be realized, although it is not stated explicitly, that the accumulation of capital and savings in the present analysis leads to a reduction in productive expenditure along with the restoration of consumption expenditure, just as in the previous analysis. This fact is present implicitly in the restoration of consumption expenditure and disappearance of net investment.

5. The Addition to the Rate of Profit Caused by Increases in the Quantity of Money

As we have seen, under an invariable money, as net investment occurs and total capital increases, the economic system becomes more and more capital intensive—i.e., capital rises relative to sales revenues, wages, and consumption. This has a profound bearing on the average rate of profit, over and above its tendency to cause a rise in net consumption and the disappearance of net investment—a bearing that applies to the rate of profit both in nominal and in real terms, and whose precise nature is the subject of this section and the next.

This further bearing on the rate of profit exists because, as we have also seen, a major effect of greater capital intensiveness is that the receptiveness of the economic system to technological progress is increased, which, in turn, can make possible continuous capital accumulation and economic progress.⁷² The relevant aspects of the process of capital accumulation and economic progress are the increasing supply of commodities in general and of the monetary commodity or commodities in particular. The effects of the latter on the rate of profit in nominal terms is the subject of this section. The effects of the former on the rate of profit in real terms is the subject of the next section. The rate of profit in nominal terms, or, simply, the nominal rate of profit, is, of course, the rate of profit as ordinarily understood, that is, the amount of money earned as profit, divided by the amount of money invested as capital. The rate of profit in real terms, or simply, the real rate of profit, is the rate of profit adjusted for changes in the purchasing power of money. It is the measure of the gain in actual wealth, if any, that is the result of the earning of any given rate of profit.⁷³

A growing supply of commodity money is the virtually inevitable accompaniment of a growing overall ability to produce, inasmuch as there is no lack of any

chemical element in nature, not even gold or silver.⁷⁴ Thus there is nothing to stand in the way of this result once net investment has succeeded in raising the degree of capital intensiveness to the point that the receptivity of the economic system to technological progress is such that continuous capital accumulation and economic progress can in fact take place.

Up to now, of course, my discussion of profits has proceeded on the assumption that increases in production take place with no connection to the quantity of money. It should be clear that this assumption needs to be modified in dealing with an economic system whose money is itself a physical commodity, such as gold or silver. The truth is, as I have pointed out repeatedly, that under a gold or silver standard, large-scale increases in production are bound to be accompanied by increases in the quantity of money and volume of spending. I will now proceed to show that the effect of this is *the addition of a corresponding positive component to the nominal rate of profit*. (In the next section, I will show how increases in the ability to produce the mass of ordinary, nonmonetary commodities add a corresponding positive component to the real rate of profit.)

Furthermore, as I have shown, in the case of any individual country using the same money as other countries, as is the case under an international gold or silver standard, the very fact of a more rapid rate of increase in physical production in that country compared with other countries will also increase the quantity of money in that country. This is because the economy of that country will come to constitute a larger proportion of the world's economic system. As a result, it will come to hold a larger proportion of the world's supply of commodity money and thus to experience rising spending and sales revenues within its own borders.⁷⁵ The effect of an increase in the quantity of money and volume of spending occurring in this way too is to add a positive component to the nominal rate of profit.

Thus, in reality, net investment and the growing capital intensiveness it causes are inherently incompatible with the assumption of a fixed quantity of money and volume of spending, if the money is a commodity money. They necessarily break the constraints of that assumption. The assumption of an invariable money is vital for purposes of economic theory, which can effectively develop its primary propositions in no other context. But the limits of the assumption must be recognized and the effects on the rate of profit of increases in the quantity of money dealt with. Only then, can the determinants of the—nominal—rate of profit be considered as fully explained.

The rate of increase in the quantity of money and, accordingly, the volume of spending in the economic

system, tends to cause *an approximately equivalent increase in the rate of profit*. For example, if the quantity of money and the volume of spending in the economic system increase by 2 percent a year, that tends to add approximately 2 percent to the rate of profit. If the quantity of money and volume of spending in the economic system increase at the rate of 5 percent a year, that tends to add approximately 5 percent to the rate of profit. In other words, if the rate of profit would otherwise have been, say, 4 percent, it will now be 6 percent or 9 percent, depending on the rate of increase in the quantity of money and volume of spending in the economic system.

This relationship follows from the very nature of the rate of profit. The rate of profit is the amount of profit earned, on an annualized basis, divided by the capital invested. For example, if a businessman spends \$100 for a quantity of merchandise which he sells one year later for \$110, his amount of profit is \$10 and his rate of profit is 10 percent. If he spends \$100 for merchandise that he sells one month later for \$101, his annualized rate of profit is 12 percent. If he spends \$100 for merchandise that he sells two years later for \$120, his annualized rate of profit is, again, 10 percent.

Now if the quantity of money and thus the volume of spending in the economic system are increasing over time, the sales revenues of the average businessman will tend to increase accordingly. If, for example, the quantity of money and volume of spending are increasing at a 2 percent annual rate, our merchant who otherwise would have sold his goods a year later for \$110, will now tend to sell them for 2 percent more, that is, for $1.02 \times \$110$, which is \$112.20. His rate of profit will thus be 12.2 percent instead of 10 percent. Similarly, the merchant who otherwise would have sold his goods one month later for \$101, will now tend to sell them for slightly more. In a period of one month, a 2 percent annual increase in the money supply and volume of spending will tend to raise his sales revenues by $\frac{1}{12}$ of 2 percent, i.e., by $\frac{1}{6}$ of 1 percent. Thus instead of selling for \$101, he will tend to sell for 1.00167 times \$101, that is, for \$101.17. When annualized, his monthly profit of \$1.17 yields a rate of profit of 14.04 percent, which is approximately 2 percent more than his initial profit rate of 12 percent. Similarly, our merchant who initially sold his goods for \$120 two years later, will now, at a 2 percent annual increase in the money supply and volume of spending, tend to sell them for $1.02 \times 1.02 \times \120 , or for \$124.85. A profit of \$24.85, when annualized, turns out to represent a rate of profit of 12.43 percent on the \$100 of capital invested. Again, the rate of profit is increased by approximately the same number of percentage points as the rate of increase in the quantity of money and volume of spending in the economic system.

Figure 16-2
The Elements Determining the Average Rate of Profit

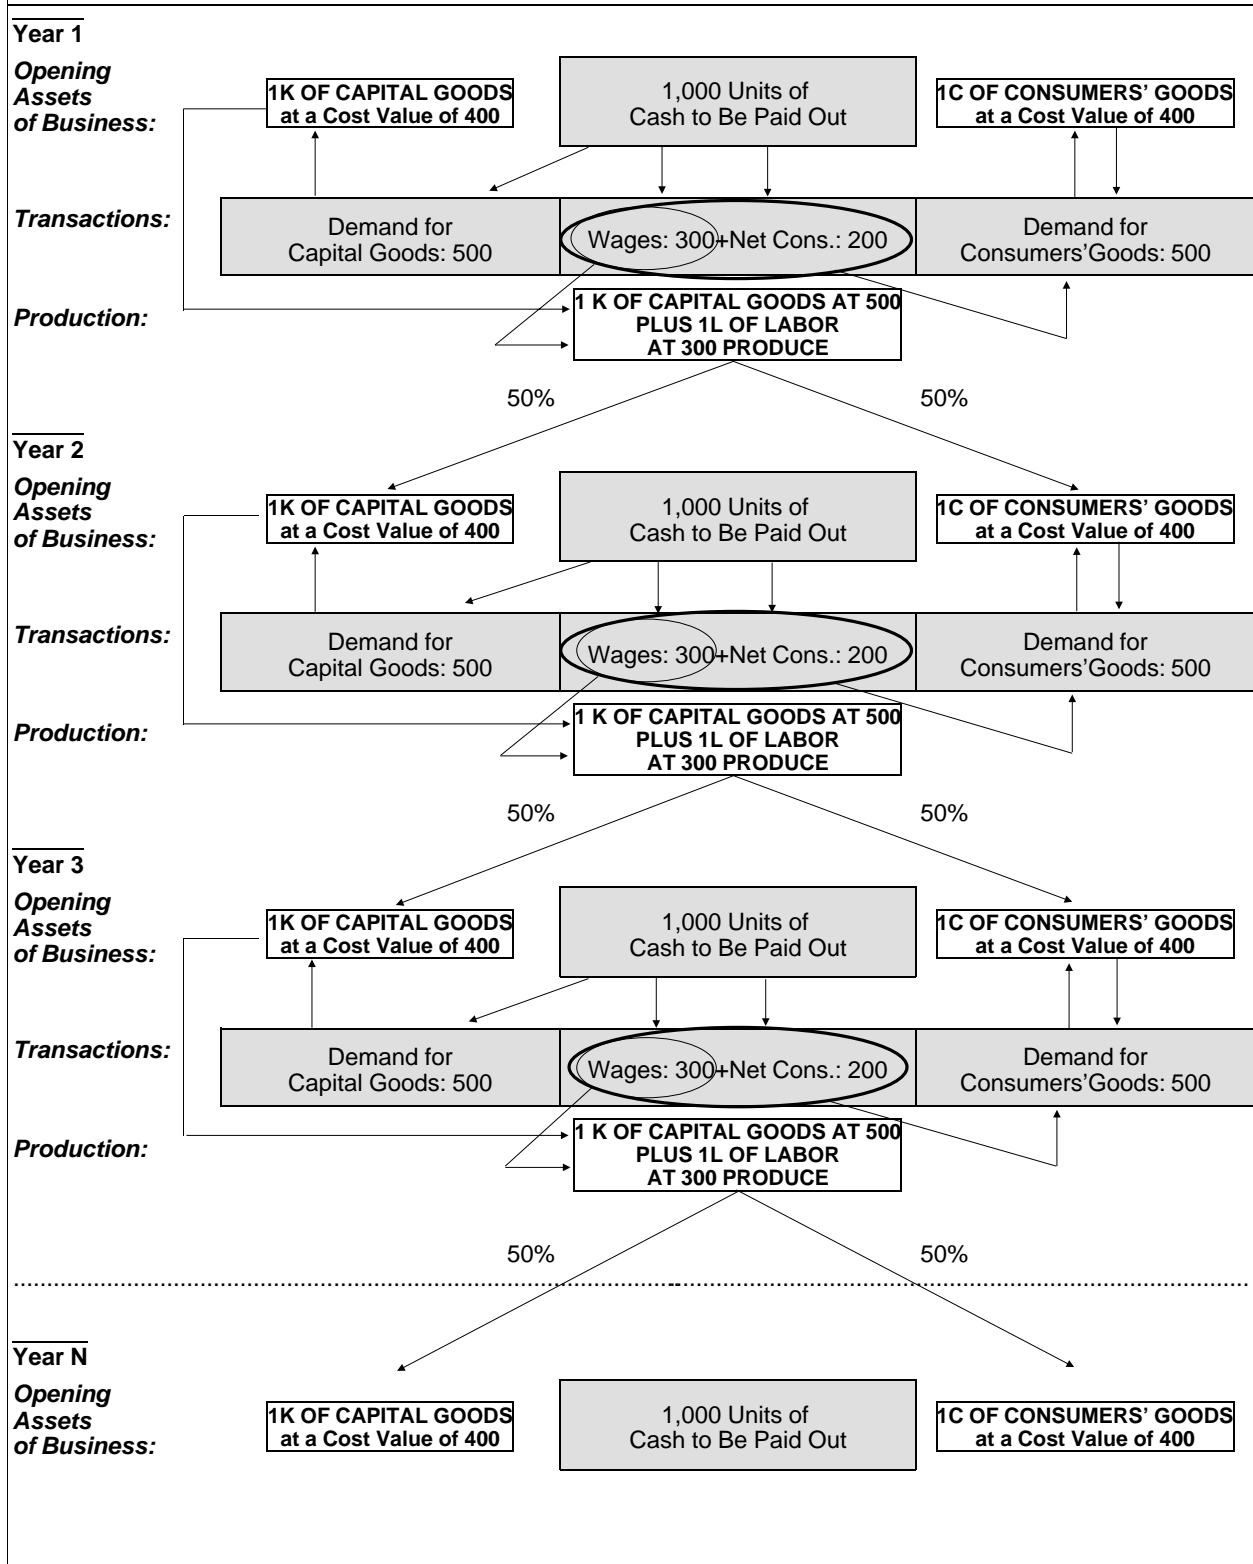

Figure 16-3

Profits in an Economy with an Increasing Quantity of Money

These results are borne out by Figure 16-3 and Table 16-11. Figure 16-3, titled "Profits in an Economy with an Increasing Quantity of Money," represents the previous Figure 16-2 but with the incorporation of the assumption that the quantity of money and volume of spending in the economic system increase at a 10 percent annual rate. (Such a large percentage increase is assumed strictly for purposes of ease of illustration. The rate of increase under a gold or silver standard would, of course, be far less.) The figure depicts a 10 percent annual increase both in net consumption and in productive expenditure, and, further, in the specific components of productive expenditure, namely, the demand for capital goods and wage payments. On the basis of the assumption that the costs deducted from sales revenues in each year represent the productive expenditure of the year before, it is possible once again to compute the annual amount and rate of profit in the economic system.

In *Year 2*, the amount of profit turns out to be 300 instead of the 200 which existed in *Year 2* of Figure 16-2, under the conditions of an invariable money. (For the sake of convenience of readers who wish to make a direct comparison between Figures 16-2 and 16-3, the former is reproduced directly facing the latter.) This is because

sales revenues, constituted by 550 of demand for capital goods and 550 of demand for consumers' goods, are 1,100, while costs, representing the 800 of productive expenditure of *Year 1*, are still just 800. In *Year 3*, with sales revenues at 1,210 and costs at 880 (the latter reflecting the 10 percent rise in demand for capital goods and labor in *Year 2*), profits rise to 330. And thereafter, the amount of profit continues to increase by 10 percent per year—that is, at the same rate as the increase in the quantity of money and volume of spending.⁷⁶

The *rate* of profit in Figure 16-3, of course, can be computed simply by dividing the amount of profit in each year by the amount of capital that has been invested up to that year. The rate of profit computed for each year of Figure 16-3 can then be compared with the 11.11 percent rate of profit previously computed for each year of Figure 16-2. The difference will then show the effect of the 10 percent annual increase in the quantity of money and volume of spending. It should be expected, of course, that the calculations will show an addition to the rate of profit of approximately 10 percent, viz., that the rate of profit will now be approximately 21 percent instead of 11 percent.

The necessary calculations are carried out in Table

Table 16-11
The Effect of an Increasing Quantity of Money and Rising Volume
of Spending on the Nominal Rate of Profit

16–11, which is appropriately titled “The Effect of an Increasing Quantity of Money and Rising Volume of Spending on the Nominal Rate of Profit.” Table 16–11 extends the data of Figure 16–3 to a fifth year. For each year, it shows the quantity of money, M , in existence at the start of the year; the percentage rate of increase in the quantity of money, ΔM , which, of course, is 10 percent; the amount of net consumption, NC ; the amount of productive expenditure, B ; the magnitude of costs deducted from sales revenues, d , which equals the productive expenditure of the previous year; the amount of net investment, I , which, of course, is equal to the difference between the productive expenditure and the costs of any given year; the magnitude of sales revenues, s , which is equal to the sum of net consumption plus productive expenditure; the amount of profit, p , resulting from the subtraction of costs from sales revenues; the amount of capital, K ; the rate of profit, r , which results from dividing the amount of profit by the amount of capital; and, finally, Δr , the difference between this rate of profit and the rate of profit prevailing in the conditions of Figure 16–2.⁷⁷

It turns out that the table shows a rise in the rate of profit from 11.11 percent in *Year 1*, which represents the conditions of Figure 16–2, to 15.79 percent in *Year 2* and thereafter. This, of course, represents a surprisingly low addition to the rate of profit of only 4.68 percent, not the approximately 10 percent that previous discussion had led us to expect.

The reconciliation of this result with the reasonable expectation of a 10 percent addition to the rate of profit is to be found in the enormously large role played by the quantity of money in the calculation of capital invested. In each year of Figures 16–2 and 16–3, the quantity of money in the possession of business firms represents over half of their total capitals. This unduly large role of the quantity of money as a component of capital results from the simplifying assumption that all spending in a year takes place on the opening day of the year and is financed out of the preexisting cash holding of business.

The effect of such a large role being assigned to the quantity of money in the calculation of capital is to add a corresponding dead weight, as it were, in the calculation of the rate of profit.

This becomes apparent if the rates of profit in Figures 16–2 and 16–3 are recalculated on the basis of a provisional exclusion of the quantity of money from capital invested. If this is done, the amount of capital in Figure 16–2 turns out to be 800 in every year, as is shown in Table 16–12. Given a 200 amount of profit in each year, the table shows that the recalculated rate of profit for Figure 16–2 in every year is 25 percent rather than 11.11 percent. Similarly, Table 16–13 shows an amount of capital of 800 in *Year 1* of Figure 16–3 and a rate of profit in that year of 25 percent. It shows the amount of capital in *Years 2* through *5* of Figure 16–3 as 800, 880, 968, and 1,065 respectively. (As with Table 16–11, both tables continue to extend the analysis of Figures 16–2 and 16–3 to a fifth year.)

When these lesser amounts of capital, reflecting the exclusion of money, are divided into the respective amounts of profit of 300, 330, 363, and 399 for *Years 2* through *5* of Table 16–13, the corresponding rate of profit turns out to be 37.5 percent in each and every year. This, of course, implies an addition to the rate of profit of 12.5 percent—which is shown in the column labeled $\Delta r\%$ —and suggests that the actual relationship between the rate of increase in the quantity of money and volume of spending on the one side and the addition to the rate of profit on the other, is that the rate of profit is elevated by a number of percentage points equal to the rate of increase in the quantity of money and volume of spending plus the product of that rate times the initial rate of profit. (The addition to the rate of profit of a further 2.5 percent, over and above the 10 percent corresponding to the increase in the quantity of money and volume of spending, equals the product of the 10 percent annual increase in the quantity of money and volume of spending times the initial rate of profit of 25 percent.)

The Impact of Increases in the Quantity of Money on the Net-Investment and Net-Consumption Rates

Further examination of the data of Figure 16–3 and Table 16–11, as recalculated in Table 16–13, shows that the increase in the rate of profit corresponds to the creation of a net-investment rate of 10 percent, which is equal to the rate of increase in the quantity of money and volume of spending, plus an increase in the net-consumption rate of 2.5 percent, i.e., from 25 percent to 27.5 percent. (Both rates, of course, are calculated on the basis of the exclusion of money from capital.)

Observe. In the conditions of Figure 16–2, there is no net investment and the net-investment rate is therefore zero. In the conditions of Figure 16–3, however, net investment equal to 10 percent of capital excluding cash commences. Thereafter, the absolute amount of net investment increases at a rate of 10 percent a year, which is the same rate as capital exclusive of cash increases. Thus net investment is 80 in *Year 2*, when capital exclusive of cash is 800; 88 in *Year 3*, when capital exclusive of cash is 880; 97 in *Year 4*, when capital exclusive of cash is 968; and, finally, 106 in *Year 5*, when such capital is 1065. In other words, the net-investment rate is 10 percent in each year. In addition, a 10 percent annual increase in the amount of net consumption raises the net-consumption rate by 10 percent of the initial net-consumption rate. The net-consumption rate is elevated in this way because the amount of net consumption in *Year 2* increases by 10 percent—i.e., from 200 to 220—before there is any increase in the amount of capital exclusive of cash. And then, in *Year 3* and thereafter, as the capital exclusive of cash increases by 10 percent per year, so too does the amount of net consumption.

On the basis of this discussion, it should be clear that the addition to the rate of profit caused by increases in the quantity of money and volume of spending does not represent the creation of a new, distinct component in the rate of profit that is separate from the net-consumption

and net-investment rates, but represents *an addition to those very rates*. In other words, the effect of increases in the quantity of money and volume of spending is to raise the rate of profit essentially by virtue of raising the net-investment and net-consumption rates. For the increase in the quantity of money and volume of spending operates to increase both productive expenditure and net consumption in proportion to itself. The growth in productive expenditure from year to year correspondingly elevates productive expenditure above costs, which reflect the productive expenditure of the year before. Thus, the increase in the quantity of money and volume of spending adds to or, indeed, creates net investment. In addition, it increases the amount and rate of net consumption. Specifically, the rate of increase in money and spending adds to the net-investment rate a number of percentage points equal to itself, and to the rate of net consumption a number of percentage points equal to the product of itself times the initial rate of net consumption.⁷⁸

Increases in the Quantity of Money and the Perpetuation of Net Investment

As we have seen, the main impact of the increase in the quantity of money on the rate of profit is by way of the net-investment rate rather than the net-consumption rate. While the increase in the quantity of money and volume of spending merely adds to the net-consumption rate, it tends to be responsible for the *whole* of the net-investment rate. Indeed, it is what keeps net investment in being. For as I have shown, in an economic system with an invariable money, net investment tends to disappear.⁷⁹ It is only the increase in the quantity of money and volume of spending that makes it possible for net investment to be a regular, permanent phenomenon.

A growing quantity of money perpetuates the existence of net investment because it results in growing outlays for the factors of production, and these outlays

are always ahead of the corresponding costs they generate. Imagine, for example, that because of a growing quantity of money, spending for plant and equipment by business rises at the rate of 2 percent per year, or at any given rate. Eventually, annual depreciation charges will also rise by 2 percent per year, or by whatever the rate at which productive expenditure for plant and equipment rises. But the depreciation charges will never catch up with the current spending for plant and equipment because they always reflect earlier such spending, which, in the nature of the case, was less. Thus, net investment occurs simply as a product of the increase in the quantity of money and the volume of spending.

To elaborate on this example, if the average life of plant and equipment is 20 years and the average rate of increase in the quantity of money and volume of spending in the economic system, including spending for plant and equipment, is 2 percent, then in 20 years, plant-and-equipment spending will equal whatever it is currently *times* 1.02^{20} . But total annual depreciation charges in 20 years will equal the summation of one-twentieth of each of twenty years' plant-and-equipment spending beginning with this year's plant-and-equipment spending and continuing on up to the plant-and-equipment spending of twenty years hence. The plant-and-equipment spending of nineteen of those twenty years is smaller than the plant-and-equipment spending of *Year 20*, in a compound proportion of 2 percent per year. Thus the depreciation quotas in *Year 20*, reflecting the division of each of these progressively smaller annual plant-and-equipment expenditures of the previous years by twenty, are correspondingly smaller. It is a question of comparing twenty depreciation terms ranging from $\frac{1}{20}$ through $\frac{1.02}{20}$, $\frac{1.02^2}{20}$ all the way up to $\frac{1.02^{20}}{20}$, with 1.02^{20} . Obviously the last term substantially exceeds the sum of the twenty depreciation terms. If it were broken into twenty equal parts, its excess would show up as the summation of

$$\frac{1.02^{20}}{20} - \frac{1}{20} + \frac{1.02^{20}}{20} - \frac{1.02}{20} + \frac{1.02^{20}}{20} - \frac{1.02^2}{20} + \dots$$

$$\frac{1.02^{20}}{20} - \frac{1.02^{20}}{20}$$

The difference is net investment in *Year 20*.

Obviously, the formula and its implications for net investment can easily be generalized to apply to any rate of increase in spending for plant and equipment of any average life, simply by substituting r for 2 percent, and n for 20 years.

It should not be difficult to see that essentially the same kind of relationship as exists between productive

expenditure for plant and equipment, and depreciation cost, exists between productive expenditure on account of inventory and work in progress, and cost of goods sold. A growing quantity of money and thus rising volume of spending on account of inventory and work in progress operates to make such productive expenditures regularly exceed cost of goods sold, which reflects earlier such expenditures, which, in the nature of the case, were smaller.

The fact that the net-investment rate tends toward equality with the rate of increase in the quantity of money and volume of spending does not depend on the assumption that the labor and capital goods of any given year are entirely used up in producing the products just of the next year. Nor does it depend on the corollary of that assumption, which is that the costs of any given year are equal simply to the productive expenditure of the year before. The tendency toward equality between the net-investment rate and the rate of increase in the quantity of money and volume of spending does not depend on the number of future years that the means of production of any given year may serve or how long it may take for the value of those means of production to show up fully in the form of costs of production. These conclusions are confirmed by Table 16–14, "The Net-Investment Rate Equals the Rate of Increase in the Money Supply."

Table 16–14 assumes the existence of plant with a 10-year life. It shows that if a constant amount of productive expenditure for such plant takes place—for the sake of illustration, 500 monetary units per year—annual depreciation cost rises to equality with such productive expenditure in 10 years. At that point net investment declines to zero and the net-investment rate becomes zero. This is after gross plant has grown to 5000 monetary units, cumulative depreciation to 2750 monetary units, and net plant to 2250 monetary units. The table then assumes that starting in *Year 11*, productive expenditure for plant rises at a 10 percent annual rate (based on a 10 percent annual increase in the quantity of money and volume of spending in general). The year-by-year implications of this are presented for annual depreciation, net investment in plant, and for the respective values of gross plant, cumulative depreciation, and net plant. Finally, the rate of net investment in plant is calculated by dividing each year's net investment in plant by the value of net plant in the year before. The table shows that under the assumed conditions, the net-investment rate reaches 10 percent—exactly the same as the rate of increase in the quantity of money and volume of spending—in *Year 19*, and remains at 10 percent in all of the remaining years covered, namely, through and including *Year 25*.

Plant of any life could be substituted for the plant of

Note: Because of rounding in the three columns, Net Investment in Plant sometimes deviates slightly from the difference between Productive Expenditure for Plant and Annual Depreciation Cost.

10 year life assumed in the table. In addition, any rate of increase in the quantity of money and annual expenditure for plant could be substituted. In all cases, it would be found that the rate of net investment ultimately came to stabilize at a rate equal to the rate of increase in the quantity of money and volume of spending. Furthermore, exactly the same kind of demonstration could be made in connection with net investment in inventory and work in progress.

The Increase in the Quantity of Commodity Money as an Addition to Aggregate Profit

Finally, the provisional exclusion of money from capital can now be abandoned, and money in the hands of business enterprises restored to the category of capital. With money restored to capital, the addition to the rate of profit will be found to correspond much more closely to the rate of increase in the quantity of money if we adopt the procedure of counting *the increase in the quantity of money itself* as constituting an equivalent addition to the amount of profit in the economic system. (I will provide the justification for following this procedure in the case of commodity money immediately following the demonstration of the consequences of following it.)

What I mean by counting the increase in the quantity of money itself as part of profits can be illustrated in terms of Figure 16–3 and Table 16–11. There the quantity of money increases by 100 units in *Year 2*, a further 110 units in *Year 3*, and so on, at a compound rate of 10 percent per year. What I am maintaining is that the addition to the rate of profit resulting from this increase in the quantity of money will be found to very closely approximate the 10 percent rate of increase in the quantity of money itself if the 100 of increase in the quantity of money in *Year 2* is added to the 300 of profit existing in *Year 2* on the basis of net consumption and net investment, and the 110 of increase in the quantity of money in *Year 3* is added to the 330 of profit existing in *Year 3* on the basis of net consumption and net investment, and so on.

If year by year, the increase in the quantity of money itself is added to the amount of profit otherwise existing in the economic system, this addition will be found to provide a rate of profit on the money supply of the year before precisely equal to the rate of increase in the money supply. For example, counting the 100 of additional money in *Year 2* as an addition to the amount of profit in *Year 2*, provides a 10 percent rate of profit on the 1,000 of money counted as capital in *Year 1*. The 110 of additional money in *Year 3* provides a 10 percent rate of profit on the 1,100 of money counted as capital in *Year 2*, and so on.

Thus the money supply of each year can be counted

as part of capital, and no matter how large a part—no matter how exaggerated its size relative to the rest of capital—the rate of profit will increase in accordance with the rate of increase in the quantity of money. This is because the money component of capital no longer operates as a dead weight, since its growth generates a further, additional component in the amount of profit in the economic system. For example, capital can be 1,800 in *Year 1*, instead of 800, and a 10 percent rate of increase in the quantity of money now brings about not only 80 of net investment in the next year and 20 of additional net consumption, but the 100 of increase in the quantity of money itself enters into the magnitude of profit and provides a 10 percent rate of profit on the 1,000 of the capital of *Year 1* that was constituted by money. And similarly in every following year. Thus, the monetary component of capital now has its corresponding profit component when the money supply grows, just as the nonmonetary part of capital has its net investment component in the rate of profit when the money supply grows.

This procedure and its implications for the calculation of the rate of profit, and for the increase in the rate of profit when the money supply grows, are elaborated in Table 16–15. This table is almost identical to Table 16–11. The only difference is that the year-by-year amount of increase in the quantity of money is shown instead of the rate of increase, and, more importantly, the amount and rate of profit—and thus the rise in the rate of profit—are calculated on the basis of the inclusion of the increase in the quantity of money in the amount of profit, alongside of the sum of net consumption plus net investment. The table shows that when recalculated in this way, the rate of profit rises from 11.11 percent to 21.05 percent, where it stabilizes, so long as the quantity of money and volume of spending go on increasing at a 10 percent annual rate. On this basis, the table shows that the recalculated addition to the rate of profit turns out to be 9.94 percent rather than the 4.68 percent of Table 16–11.

In addition, the last three columns of the table show, by means of a second line appearing for each year, that if the monetary component of capital were taken as the money supply of the year before, the addition to the rate of profit would conform *exactly* to the formula previously elaborated. Namely, to the formula that an increasing quantity of money tends to add a component to the rate of profit equal to the rate of increase in the money supply plus the product of that rate of increase times the rate of profit that would prevail in the absence of an increase in the money supply. For it shows that when calculated in this way, the rate of profit would rise from 11.11 percent to 22.22 percent. This rise in the rate of profit is precisely equal to the sum of the 10 percent rate of increase in the money supply plus 10 percent of the

Table 16-15

The Effect of an Increasing Quantity of Money and Rising Volume of Spending on the Nominal Rate of Profit When the Increase in the Quantity of Money Is Added to the Amount of Profit

YEAR	<i>M</i>	ΔM	<i>NC</i>	<i>B</i>	<i>d</i>	<i>I</i>	<i>s</i>	$\frac{p}{NC+I+\Delta M}$	<i>K</i>	<i>r</i> %	Δr %

KEY: ** Ignores effects of rounding*

M = Money Supply. *s* = Sales Revenues.

ΔM = The Increase in the Money Supply. *p* = Profits.

NC = Net Consumption. *K* = Capital.

B = Productive Expenditure. *r* = The Rate of Profit.

d = Costs Deducted from Sales Revenues. Δr = The Increase in the Rate of Profit.

I = Net Investment (*B*-*d*).

11.11 percent rate of profit prevailing in the absence of an increase in the money supply. It is precisely equal to the sum of the 10 percent rate of net investment that is generated plus the increase in the rate of net consumption that is brought about by the 10 percent rate of increase in the quantity of money.⁸⁰

Now the procedure of counting the increase in the supply of money as a direct addition to the amount of profit in the economic system can be fully and readily justified in the case of a commodity money. Under a commodity money system, the quantity of gold and silver mined is the equivalent of sales revenues from the perspective of the gold and silver mining concerns. For example, the revenues of a gold mine under a gold standard are the gold it mines. Under a gold standard, a gold mine mines money, and the money it mines is for it the full equivalent of sales revenues.

Of course, gold and silver mines incur substantial costs, and these costs must be subtracted from the bullion revenues of these mines in determining their profits. Indeed, the profits of the money-mining concerns tend to be no greater in relation to capital invested than profits

in any other branch of production, and thus do not remotely equal the quantity of money they mine. Nevertheless, under a commodity money, profits in the economic system as a whole do in fact tend to be elevated by the full amount of the money that is mined.

This is because to the extent that the money-mining concerns make productive expenditures and incur corresponding costs, the magnitude of productive expenditures and costs in the rest of the economic system is correspondingly reduced, and thus the magnitude of profits in the rest of the economic system is correspondingly increased. In other words, the devotion of resources to gold and silver mining, to earn the bullion revenues of these industries, equivalently reduces productive expenditure and costs in the rest of the economic system, whose sales revenues are what they are and whose profits are therefore correspondingly increased by the reduction in its productive expenditures and costs. In this way, an increase in the quantity of commodity money, in constituting revenues of the gold and silver mining concerns, constitutes in part the equivalent of the profits of these concerns and, for the rest, the equivalent of a reduction

in the costs and rise in the profits of concerns elsewhere in the economic system, whose productive expenditures and costs are less to the extent that productive expenditures and costs exist in gold and silver mining.

To put matters in still a somewhat different way, the bullion revenues of the money-mining concerns represent not only the equivalent of sales revenues to them, but the equivalent of a precisely equal addition to the aggregate sales revenues of the economic system, in the face of the same magnitudes of productive expenditure and cost in the economic system. The mining of commodity money, thus turns out to be very similar in nature to the existence of a further increment of net consumption, for it is a source if not of an excess of literal sales revenues over productive expenditure, then at least of an excess of sales revenues plus the virtual equivalent of sales revenues—i.e., mined bullion revenues—over productive expenditure.

For these reasons, in the case of commodity money, the procedure of treating the addition to the quantity of money as a direct addition to the amount of profit is fully justified.

In the case of a fiat paper money, of course, it is inappropriate to add the increase in the quantity of money itself to the amount of aggregate profit in the economic system. This is because the increase in the quantity of fiat paper money is not at all analogous to the sales revenues of a business. It is the fruit of a virtual counterfeiting operation, not of any kind of productive venture. Nevertheless, it should be realized that even in this case, the deviation between the increase in the rate of profit caused by the increase in the quantity of money and the rate of increase in the quantity of money itself is far less in reality than is indicated in Table 16–11. This is because the quantity of money in the real world is much smaller in relation to capital and the volume of spending than it is in Figures 16–2 and 16–3, and thus in Table 16–11, which is based on them. As a result, the significance of the “dead weight” constituted by counting the quantity of money in capital is correspondingly reduced. The resulting rates of profit and of changes in the rate of profit, therefore, much more closely approximate those of Tables 16–12 and 16–13, in which money is altogether excluded from capital, than those of Table 16–11, in which it looms so large. For example, if the quantity of money entering into capital had been a tenth of sales revenues instead of equal to sales revenues in Figures 16–2 and 16–3 and in Table 16–11, the resulting rate of profit in each year would have approximated the rates calculated in Tables 16–12 and 16–13.

The statement, earlier in this section, of the effect of increases in the quantity of money on the rate of net

consumption in terms of a strict proportionality was almost certainly inaccurate. An increase in the quantity of money would not in fact directly and immediately increase net consumption in proportion to itself, as was assumed, for the sake of simplicity, in Figure 16–3 and the various tables developed on the basis of it. The immediate effect of the increase in the quantity of money on net consumption might well be limited to the extent to which the additional money was perceived as an addition to accumulated wealth. Nevertheless, there is some effect, and one which becomes the greater and more significant, the more rapid is the increase in the quantity of money and volume of spending. The discussion of the consequences of inflation in Chapter 19 provides a variety of grounds for this claim.⁸¹

The fact that the increase in the quantity of money and volume of spending does operate to raise the rate of net consumption, and does so to the degree that the increase in the quantity of money is the more rapid, constitutes a powerful argument for a monetary system in which the increase in the quantity of money is strictly limited. Such a monetary system adds 1, 2, or 3 percentage points through the increase in the quantity of money to the rate of profit which would otherwise be established by the rate of net consumption alone. It thus serves to provide a sufficient incentive to invest money rather than hold it, even in the face of extremely low rates of net consumption—rates of net consumption on the order of 2 or even 1 percent. At the same time, with such modest rates of increase in the quantity of money, it does not serve significantly to raise the rate of net consumption. It thus achieves the possibly important benefits of a higher nominal rate of profit without any significant negative effects.

Such a monetary system, of course, is the 100-percent-reserve gold standard (or parallel 100-percent-reserve gold and silver standards), which compels strict limitation of the increase in the quantity of money to the modest rate of increase in the supply of precious metals.⁸²

Summary Statement of the Determinants of the Rate of Profit

To summarize the determinants of the rate of profit: The rate of profit is determined by and equal to the sum of the rate of net consumption plus the rate of net investment. It can also be expressed as tending to equal, as an approximation, *the sum of the rate of net consumption plus the rate of increase in the quantity of money and volume of spending*. For the rate of increase in the quantity of money and volume of spending tends to generate an equivalent rate of net investment and, in the long run,

to be the only source of net investment.

The increase in the quantity of money and volume of spending also, of course, tends to raise the rate of net consumption. While it may not do so by the product of itself times the rate of net consumption prevailing in the absence of an increase in the quantity of money, it does so at least to some extent, and one which becomes the more significant, the more rapid is the rate of increase in the quantity of money and volume of spending.

The inclusion of money in capital does not materially affect the accuracy of the proposition that the rate of profit is elevated by a percentage approximately equal to the rate of increase in the quantity of money. In the real world, the quantity of money held by business is small relative to capital and sales revenues, and thus the "dead weight" aspect of counting money in capital is minimal. Moreover, under a 100-percent-reserve gold standard, the increase in the quantity of money would itself properly enter into the calculation of total profit and thus completely offset the otherwise dead weight aspect of counting money in capital.

The amount and rate of profit is ultimately determined on the basis of time preference operating through the rate of net consumption, the marginal productivity of capital operating through the rate of net investment, and the rate of increase in the quantity of money operating through both the rate of net investment and the rate of net consumption, though primarily through the former.

6. Increases in the Real Rate of Profit Dependent on Increases in the Production and Supply of Goods

The rate of profit to which increases in the money supply and volume of spending contribute is, of course, the nominal rate of profit, i.e., the rate of profit expressed simply in terms of money. This rate of profit, as everyone should now know, is by no means necessarily equal to the actual rate of gain—the real rate of profit—that businessmen experience, that is, to the rate of increase in their ability to purchase actual physical wealth. This is because it is entirely possible, and very frequently happens, that the same increase in the quantity of money and volume of spending that raises the nominal rate of profit, equivalently raises prices, with the result that absolutely no rise in the real rate of profit occurs. For example, a 2 or a 10 percent increase in money and spending may well succeed in raising prices by 2 or 10 percent at the same time that it adds 2 or 10 percent to the nominal rate of profit. If that happens, then even if someone adds the whole addition to his nominal profit to his capital and thus becomes worth 2 or 10 percent more in terms of money than he was before, he still has not gained anything whatever in terms of buying power. His larger

nominal capital is capable of buying no more than was his original nominal capital.

Usually, these are the facts which must be stressed, so that people will realize that a nominal rate of profit of any given percentage by no means implies a corresponding increase in the ability of businessmen to buy goods. In the present context, however, what must be stressed is the fact that *under a commodity money*, the addition to the nominal rate of profit caused by the increase in the quantity of money not only can be, but typically is, accompanied by an equal or even greater increase in the real rate of profit. This becomes apparent when one realizes that the relationship between the nominal and the real rate of profit depends on the relationship between the rate at which the quantity of money and the volume of spending increase, on the one side, and the rate at which production and the supply of goods increase, on the other. If, for example, when the quantity of money and volume of spending increase at the rate of 2 percent per year, the production and supply of goods also increase at the rate of 2 percent per year, then prices on average will be stable. As our price level formula shows, 1.02 times the spending will buy 1.02 times the production and supply at an unchanged level of prices. Thus, in this case, the 2 percent addition to the nominal rate of profit caused by the increase in money and spending will also represent a 2 percent addition to the real rate of profit, because, at the same time, production and supply have increased at a 2 percent annual rate and have thus kept prices stable.

It is implied in this example that just as increases in the quantity of money and volume of spending add to the nominal rate of profit, so increases in the physical production and supply of ordinary, nonmonetary commodities add to the real rate of profit. The increase in the nominal rate of profit achieved by any given rate of increase in the quantity of money and volume of spending represents an increase in the real rate of profit only if it is accompanied by an equivalent rate of increase in production and supply. For only that will keep prices stable and thus allow the extra nominal profits to represent corresponding additional buying power.

It is no less implied that increases in production and supply can increase the real rate of profit *without* corresponding increases in the quantity of money and volume of spending, and thus without corresponding increases in the nominal rate of profit. If, for example, the nominal rate of profit were 5 percent with no increase in the quantity of money and volume of spending, and production and supply increased at an annual rate of 2 percent, then prices would fall approximately 2 percent per year. A businessman who began a year with \$100 and finished it with \$105 would have an increase in real wealth not of

5 percent, but of approximately 7 percent, because his \$105 would go about 7 percent further than his initial \$100 at prices only 98 percent of what they were at the start of the year.

What we have here is a kind of "Say's Law of Profits"—namely, that the rate of increase in production and supply adds to the real rate of profit, while the rate of increase in the quantity of money and volume of spending adds only to the nominal rate of profit. More money and spending raise the nominal rate of profit, but are accompanied by a rise in the real rate of profit only insofar as there is an increase in the production and supply of goods. On the other hand, an increase in the production and supply of goods raises the real rate of profit, whether accompanied by an increase in the quantity of money and volume of spending or not.⁸³

It must always be kept in mind that the addition to the nominal rate of profit caused by more money and spending, and the addition to the real rate of profit caused by more production and supply, are separate and distinct elements, even though they are related under a system of commodity money. They certainly need not proceed at the same pace. There can be prolonged periods in which the increase in the production and supply of ordinary goods exceeds the increase in the supply of money and volume of spending. In such periods, the weighted average of prices falls, and the real rate of profit correspondingly exceeds the nominal rate of profit. If, on the other hand, the rate of increase in the supply of money and volume of spending exceed the rate of increase in the production and supply of goods, the weighted average of prices rises and the nominal rate of profit correspondingly exceeds the real rate of profit. The nominal rate of profit is always related to the real rate of profit in the following way: Namely, the nominal rate of profit plus the fall in prices or minus the rise in prices equals the real rate of profit.

A major principle which stands out is that increases in production and supply always raise the real rate of profit and, under a system of commodity money, by virtue of encompassing increases in production in mining in general and in precious metal mining in particular, also operate, at least to some significant extent, to raise the nominal rate of profit as well. The principle is that *under a system of commodity money, increases in production and supply raise both the real and the nominal rate of profit*. And it follows that the more rapidly production and supply can be made to increase under a system of commodity money, not only will the nominal and real rates of profit both be higher, but so too will be the *proportion* of nominal and real profits which is the result of increases in production and supply. In a rapidly progressing economic system that is based on a commodity

money, the greater part of profits, both nominal and real, may well be the result of nothing more than the rate of increase in production and supply.⁸⁴

There is reason for thinking that under a 100-percent-reserve gold or silver standard, the real rate of profit would typically be above the nominal rate of profit, i.e., that the increase in the production and supply of goods would exceed the increase in money and spending, with the result that prices would normally fall. Such a situation could be expected to be typical because of the difficulties of increasing the production of the precious metals in comparison with the possibilities of increasing production in the rest of the economic system, including the possibility of adding to the list of what constitutes useable natural resources and of extending the range of products that can be produced from many of the useable natural resources already known.

A further major implication of the present discussion is that the inverse relationship that has been shown to exist between economic progress, on the one side, and both nominal national income and the amount and rate of nominal profit, on the other, does not apply to the conditions of a gold or silver money. In these conditions increases in the quantity of money appear as a by-product of the same process which increases the supply of ordinary goods, and are normally within the limit of those increases. As a result, under a gold or silver money, the growing supply of goods which represents economic progress is accompanied by a rising volume of spending, based on a growing supply of gold or silver money which itself is part of the growing supply of physical goods. It is thus accompanied both by an addition to the amount and rate of nominal profit and by rising money incomes of all types.

The inverse relationship between the rate of profit and economic progress pertains to the conditions both of an invariable money and of increases in the quantity of money at rates more rapid than the increase in the supply of a gold or silver money. It does not pertain to the conditions of a gold or silver money under normal circumstances.

Net Investment Without Increasing Capital Intensiveness

Under the conditions of a gold or silver money, the nominal net investment that results from increases in the quantity of money normally represents equivalent or even more-than-equivalent *real* net investment. For it represents an addition to the nominal capital of business firms which is accompanied either by no rise in the prices of capital assets on average or, indeed, by a fall in those prices, resulting from the increase in the production of capital goods outstripping the increase in the monetary

demand for them. Such net investment is certainly real net investment, not merely nominal net investment.

Insofar as this additional real net investment represents an increase in the quantity of physical capital goods employed per worker, it can be viewed as constituting an increase in *physical* capital intensiveness. It is important to realize, however, that it does not constitute an increase in capital intensiveness in the dimension of relative monetary values—that is, in the sense of a rise in the ratio of capital expressed in money to consumption expenditure, or to sales revenues or wage payments. The relative-value dimension of the concept of capital intensiveness is the one which reflects the degree of provision for the future that is made relative to current consumption—that is, the degree to which people save and accumulate capital relative to consuming. It is the dimension to which special attention must be paid in connection with many of the leading problems of economic theory, such as whether or not capital accumulation causes or presupposes a fall in the rate of profit. The relative-value dimension, of course, is the dimension in which I have been primarily measuring capital intensiveness all along.

To be sure, the real net investment that takes place under a gold or silver money in conjunction with nominal net investment, presupposes the existence of a sufficiently high degree of capital intensiveness in the relative-value sense to inaugurate and maintain a process of rising production, including, above all, the production of growing quantities of capital goods. Indeed, my discussion of the effects on the rate of profit of an increase in the quantity of money began with the recognition that the growing capital intensiveness brought about by net investment in the context of an invariable money results in rising production, including the production of the monetary commodities gold and silver.⁸⁵ It was this which required my temporarily setting aside the assumption of an invariable money. Nevertheless, the nominal and real net investment which themselves result from the inauguration and maintenance of a sufficiently high degree of capital intensiveness in the relative-value sense do not themselves constitute the achievement of any greater degree of capital intensiveness in this sense.

In its nominal aspect, the resulting derivative net investment, if it can be called that, actually serves merely to maintain the existing, sufficiently high degree of capital intensiveness in the relative-value sense. This is because the same increase in the money supply that is responsible for this net investment, also operates to raise total wage payments, consumption expenditure, and total business sales revenues. Thus the growing nominal capital that such net investment achieves does not mean a rise in nominal capital *relative* to wages, consumption expenditure, or sales revenues. Only in the context of an

invariable money does an increase in nominal capital automatically mean an increase in capital intensiveness in the relative-value sense. It certainly does not mean it in the context of an increasing quantity of money, in which the magnitudes that it must be taken relative to also increase, and do so as the result of the very same cause, namely, the increase in the quantity of money.

Along the same lines, notice that this derivative net investment goes on without any increase in the average life of the assets purchased by business. As I have shown, in an economy with a constant quantity of money and volume of spending, net investment can continue only by virtue of such things as devoting a larger and larger proportion of the outlays for factors of production to plant-and-equipment purchases as opposed to expensed expenditures and purchases of labor and materials to produce inventories, and to purchases of plant and equipment of longer life rather than shorter life.⁸⁶ However, this is not true of the net investment which is the result of a growing quantity of money and volume of spending. Such net investment is the result of growing outlays for assets of all descriptions, without any necessary change in favor of such things as spending for plant and equipment or longer-lived plant and equipment.

This net investment continues in its nominal aspect by virtue of the fact that rising productive expenditure, based on a growing quantity of money, tends always to be ahead of costs deducted from sales revenues, which costs reflect the necessarily smaller productive expenditures of previous years.⁸⁷ At the same time, in its real aspect, what is present is a growing supply of capital goods from year to year that stands in the same overall quantitative and temporal relationship to the consumers' goods it will ultimately help to produce as did the smaller supply of capital goods of the year before.⁸⁸ Thus, there is no greater capital intensiveness in terms either of the ratio of the money value of capital to consumption expenditure, sales revenues, or money wages, or of the ratio of the physical supply of capital goods to the supply of consumers' goods that will ultimately result from the supply of capital goods. The only sense in which there is more capital intensiveness is that of the ratio of the supply of capital goods to the supply of labor, and that is essentially the same as the resulting rise in the ratio of consumers' goods to the supply of labor, i.e., the same as the rise in the productivity of labor.

Capital-Saving Inventions

The fact that capital accumulation can occur without increases in capital intensiveness in the relative-value sense—namely, as the result of technological progress taking place in conjunction with a sufficiently high existing degree of capital intensiveness in the relative-

value sense—should not, of course, be taken as in any way diminishing the importance of capital accumulation. Nevertheless, because the role of technological progress in capital accumulation is generally unperceived, the conviction prevails that capital accumulation is synonymous with greater capital intensiveness in the relative-value sense. Thus, when it is observed that the enormous increase in production that has taken place over the last century or more has not been accompanied by a significant increase in the degree of capital intensiveness in the relative-value sense, the conclusion is drawn that capital accumulation is of relatively little significance and that practically all of the credit for the increase in production should go to technological progress and increases in the productivity of the factors of production, *as opposed to capital accumulation*.⁸⁹ The alleged lack of need for capital accumulation to achieve economic progress is then attributed to “capital-saving inventions,” which allegedly make it possible to produce more and more without additional capital or with only relatively little additional capital.

Now a capital-saving invention can mean either of two things: An invention that makes it possible to produce a given product at a reduced *expenditure* for factors of production, or an invention that makes it possible to produce a given product by employing a smaller physical quantity of capital goods. In the context of a progressing economy under an invariable money, virtually every invention would be a capital-saving invention in the first sense, for in such an economy there would be an ever greater quantity of products produced without any necessary increase in the sum of capitals invested. Little need be said about capital-saving inventions of this sort. They would simply reflect the falling prices of capital goods and the reduced quantities of labor required in the production of products of any given type. Such inventions, of course, would not in any way imply the use of a smaller quantity of capital goods. Indeed, while ever falling expenditures of money capital were made for given quantities of capital goods, the same aggregate expenditures of money capital would be made for continually increasing quantities of capital goods. However, capital-saving inventions in the second sense, that is, in the sense of a saving of physical capital goods, do require some discussion, inasmuch as it is they which are cited in order to belittle the role played by the accumulation of capital in economic progress.

First of all, it must be realized that such inventions are the exception rather than the rule. If we compare the Middle Ages or any intervening period with the present, it at once becomes apparent that the economic progress of the Western World is overwhelmingly due to the accumulation of a larger supply of capital goods per

capita, and not to an economization of the same supply. It is not the case that the supply of capital goods per capita is today the same or not significantly larger than it was in the Middle Ages, only today instead of being embodied in ox carts, simple forges, deer skins, and primitive looms, it is embodied in machinery and materials of greater physical economy. The progressive rise in the standard of living has at each step of the way been made possible by an expansion in the supply of capital goods. Decade by decade, the physical supply of capital goods produced has risen. Had it not, the subsequent increases in the supply of consumers' goods could not have taken place. The increases merely in iron and steel production, in coal production, in trees felled, in wheat produced, and the indispensable role played by the larger supplies of these commodities in subsequent production should be sufficient to dispel any illusions on this score. To produce a larger quantity of iron and steel consumers' goods, a larger quantity of iron and steel capital goods is required. To produce more bread, more wheat is required. To build more and larger houses, more lumber or bricks is required.

In certain cases, of course, it is possible to discover methods of physically economizing on the use of materials. A change in women's fashions may eliminate several square feet of cloth from a dress; an improvement in the design of an automobile engine (assuming the engine itself does not require a larger quantity of capital goods in its own production) may make possible an economization of gasoline and petroleum. Household furniture may be less-cumbersomely designed. Economic progress, however, consists relatively little in making it possible to derive greater advantage from the same quantity of materials. For the far greater part, it consists in increasing the supply of materials. This is because there is a limit to how much cloth can be removed from a dress, to how much mileage can be obtained from a gallon of gasoline, and to how much wood can be removed from furniture. With economic progress, the cloth in the wardrobe of the average woman increases; motorists consume larger quantities of gasoline, requiring larger quantities of petroleum; the individual acquires larger quantities of furniture containing more wood in total. To make this possible, the production of the necessary capital goods must be increased. This principle applies even in the case of computers, where today a relatively small desktop computer has power comparable to that of a room-sized mainframe computer of a generation ago. This is because in place of a few hundred or a few thousand room-sized computers, there are now tens of millions of the desktop computers.

Frequently, what appears to be a saving of capital goods is not. One should not confuse the reduction in the physical quantity required merely of one capital good with an overall reduction in the quantity of capital goods

required to produce a product. And above all, one should not confuse a reduction in the physical size of a capital good with a reduction in the quantity of capital goods it represents. It may be that the capital good now contains a more valuable material embodying a larger quantity of labor in its own production. For example, if the reduction in the size, let us say, of a machine is accomplished by reducing the iron content of the machine, but also involves the use or added use in some way of platinum wire, the machine may very well represent a larger quantity of capital goods than previously, for it may now be the product of a larger quantity of labor. Or again, even if the machine represents the same physical quantities of all materials save one, which has decreased in quantity, e.g., iron ore, but that one has now undergone a higher degree of processing than previously, no real reduction in the quantity of capital goods may be involved; for that smaller quantity of ore, in undergoing a higher degree of processing, may have had as much labor expended upon it as the larger quantity of ore which did not undergo as high a degree of processing. Furthermore, insofar as the product requires the use of more advanced capital goods in its production, that too is a case of needing a larger supply of capital goods. Thus, the tens of millions of today's personal computers require a larger supply of capital goods in their production than the comparative handful of mainframe computers of the past, not only in the sense of requiring a larger overall physical volume of materials, but also in the sense of requiring the existence of more advanced computer processors, memory chips, and so forth. Improvements in the quality of capital goods is a major aspect of capital accumulation and is to be regarded as an increase in the supply of capital goods.

Finally, even in those cases in which a genuine saving of capital goods does take place, the effect most likely is to increase the supply of capital goods. This is because insofar as capital goods are employed in the production of capital goods, the fall in the amount of capital goods needed per unit of output implies an increase in the production of capital goods. This can easily be demonstrated by using any of our illustrations of the relative production of capital goods and consumers' goods, such as Figure 16-2, and by assuming an all-round flood of inventions that save capital goods. If the same total output could be produced with, let us say, half the quantity of capital goods, then the employment of the same quantity of capital goods must result in a larger total production; indeed, on the assumption of constant returns to capital goods (at the now higher level), a doubled total production. If the relative production of capital goods is unchanged, this means the production of twice the supply of capital goods as would otherwise have been produced.

Thus, if in the absence of the capital-saving inven-

tions, quantity K of capital goods together with the fixed quantity L of labor would have produced IK of capital goods and IC of consumers' goods, they now produce $2K$ of capital goods and $2C$ of consumers' goods. What is present is merely nothing other than an enormous increase in the efficiency of the economic system in using existing capital goods. No more potent source of capital accumulation could be found. It follows that such capital-saving inventions as have occurred have simply further contributed to the process of capital accumulation and its overwhelming role in increasing production and the standard of living.

The studies which belittle the role of capital accumulation in increasing production commit the further error of taking the rate of return on capital as the measure of the physical contribution of capital goods to production—as the measure of the marginal net physical productivity of capital goods rather than of the marginal productivity of capital as I have used the term.⁹⁰ Such an approach ignores the fact that the supply of capital goods is responsible for well over 99 percent of the productivity of labor—for all of the additions to the productivity of labor that have taken place since caveman days, because none of these additions would have been possible without the increase in the supply of capital goods.⁹¹

To some extent, those who deprecate the importance of additional capital in increasing production may be led to do so because of their mistaken views concerning what constitutes an increase in output. As I have shown, using national income as the measure of output, which is the almost universal practice, leads to the fallacy of viewing a fall in the demand for capital goods and rise in the demand for consumers' goods, which has the effect of increasing national income, as the cause of an increase in output, when in fact its effect is to diminish the increase in output or, if carried far enough, cause a progressive decline in output.⁹² In addition, as I have also shown, using national income as the measure of output implies that output increases to the extent that taxes are increased and the resulting increase in revenue is expended in enlarging the government's payroll, something which in reality also operates to decrease production.⁹³ The result of these confusions is that the very process of decline in capital formation and the increase in real physical wealth is misidentified as an increase in the efficiency of the economic system on the grounds that the amount of capital required to generate a unit of national income has been reduced.

7. The Inherent Springs to Profitability

This chapter has shown how the productive process generates its own profitability through net consumption

and net investment. It has shown how net investment in the context of an economy with an invariable money, in raising the degree of capital intensiveness, lays the foundation for capital accumulation and rising production and thereby an increasing quantity of commodity money. It has shown how this last, in raising the level of spending from year to year, both perpetuates net investment and adds a corresponding positive component to the rate of profit.

What must be realized now is that these sources of profit are virtual *springs* to profitability, which operate to restore profitability whenever it might temporarily be lacking for any reason (notably, because of a financial contraction and ensuing depression). Insofar as net consumption exists—and it must exist, whenever savings have been accumulated in a sufficient ratio to income and consumption—the only thing which can prevent the existence of an aggregate profit is *negative net investment*, which certainly cannot be more than a temporary phenomenon. An increasing quantity of money and rising volume of spending, the by-product of capital accumulation and increasing production, also cannot fail to reestablish profitability.

The potential for net investment, which always exists, constitutes an even more powerful spring to profitability, one whose power increases as the prevailing rate of profit decreases. Whenever aggregate profitability is lacking, not only is net investment sufficient to restore it, but, in addition, as I will show, net investment is more and more encouraged by the fact that *the lower is the rate of return on capital, the higher is the degree of capital intensiveness that pays*, and thus the more powerful is the stimulus to the existence of net investment, as the means of achieving a higher degree of capital intensiveness. Thus, the economic system is so constituted that if the rate of profit should ever become unduly low, or disappear, that very fact encourages a move toward further capital intensiveness and thereby the calling into being of net investment, which restores the rate of profit. Once I have demonstrated these propositions concerning net investment, it will be possible not only better to understand what causes and perpetuates depressions and unemployment, but also to appreciate just how alien such phenomena are to the actual nature of a capitalist economy.

In order to understand the principle of potential additional net investment serving as a spring to profitability, the context of discussion must be carefully defined. The context is the general rate of profit in the economic system as a whole. More than that, it is the general rate of profit in the economic system as a whole as determined apart from changes in the quantity of money and the overall volume of spending. In other words, it is the rate of profit insofar as it is determined by the rate of net

consumption and by the rate of net investment apart from changes on the side of money.

The naming of the first proviso, that it is the general rate of profit in the economy as a whole that is under consideration, should make it possible to avoid committing the fallacy of composition and making an invalid generalization from the consequences of a low rate of profit in an individual industry to the consequences of a low rate of profit in the economic system as a whole. In the case of an individual industry, a low rate of profit means a low rate of profit relative to rates of profit in other industries. The effect of this, of course, is to discourage investment in that industry, indeed, to encourage the withdrawal of capital previously invested. But the context under discussion here is not that of a low rate of profit in a particular industry relative to the rate of profit in other industries. It is that of a low rate of profit prevailing throughout the economic system. If this is kept in mind, then it will not be difficult to see how in these conditions, a low rate of profit actually works to encourage more capital investment rather than less.

To understand this principle, let us consider a number of concrete cases from which we can abstract the essential foundations of the principle. Let us consider, first, the case of a railroad company which is contemplating whether it should construct its line straight through a mountain by digging a tunnel, or detour around the mountain. Digging the tunnel, we assume, constitutes the more-capital-intensive method in that it requires a greater initial capital investment than the alternative. But once in existence, the tunnel would make possible, virtually forever, an annual saving in operating costs, because it would reduce the time required for trains to reach their destination. In reaching its decision, what the railway company considers is how much money the tunnel would potentially save it every year on the basis of savings of train-crew time, fuel consumption, and wear and tear of rolling stock, versus how much more it must invest to construct the tunnel in comparison with the less-capital-intensive detour around the mountain.

The railroad company will decide in favor of the tunnel if the annual savings the tunnel achieves are, when divided by the extra capital its construction requires, greater than the going rate of profit on capital. It will decide against the tunnel if the savings the tunnel achieves are, when divided by the extra capital its construction requires, less than the going rate of profit on capital. For example, imagine that the existence of the tunnel would make possible an annual saving in operating costs of \$1 million per year in comparison with the alternative route, and that at the same time, the construction of the tunnel requires \$10 million more of capital investment than the alternative route. In this case, the railroad company will

decide in favor of the tunnel if the going rate of return on capital is less than 10 percent. It will decide against the tunnel if the going rate of return on capital is more than 10 percent. This is because its investment in the tunnel will yield a rate of return of 10 percent (\$1 million per year divided by \$10 million). Whether or not this investment should be undertaken depends on a comparison of its profitability with the profitability of other investments. If the profitability of other investments is greater than 10 percent, then the capital that might be devoted to this investment should instead be devoted to them. If, on the other hand, the profitability of other investments is less than 10 percent, then this investment represents the better alternative, and it should be undertaken.

The essential point here is that the lower is the general rate of return on capital, the better does this particular investment appear by comparison. With a general rate of return of greater than 10 percent, this particular investment is submarginal—that is, it is insufficiently profitable to be undertaken. With a general rate of return of 10 percent, it becomes borderline. With a general rate of return of less than 10 percent, it becomes relatively attractive, and more and more so, the further below 10 percent the general rate of return falls. And as the general rate of return falls below 10 percent, still other investments become attractive by comparison. Capital-intensive improvements representing annual savings in cost equal to only 9 percent, 8 percent, 7 percent, and so on, successively become relatively attractive as the general rate of return falls below these levels. And not only in railroading, of course, but in every area of the economic system. In effect, the general rate of return operates as a standard, a test, which each particular capital-intensive improvement must pass in terms of the size of the annual cost reductions it achieves relative to the additional capital it requires. As the general rate of return falls, the standard—the passing grade, as it were—is reduced, with the result that a growing number of capital-intensive investments become relatively profitable, and the degree of capital intensiveness that pays is increased throughout the economic system. Furthermore, what applies to cost reductions applies equally to quality improvements. The additional revenues derived from these, relative to the additional capital that needs to be invested to achieve them, becomes less and less, as the general rate of return falls.

It pays to examine the same principle at work in another example. Thus, imagine a product that can be produced in a given quantity by any of three different methods of production, representing three different degrees of capital intensiveness. (The differences in capital intensiveness can be taken as reflecting different combinations of production by hand or by machine. The most-

capital-intensive method uses the most machinery. The least-capital-intensive method uses the least.) We call these three methods, simply, A, B, and C. As shown in Table 16–16, method A is the least capital intensive, but also the most costly. It requires an investment of \$10,000 of capital and results in \$9,000 of annual costs to produce a given quantity of the product. Method B requires \$20,000 of capital to produce the same quantity of the product but enables production to take place at an annual cost of only \$8,000. Finally, method C requires \$30,000 of capital to produce the same quantity of the product but enables production to take place at the still lower annual cost of only \$7,000.

In the conditions of this example, as the revenue derived from the sale of a given quantity of the product declines, and thus, in the face of given costs, reduces profitability, the effect is to favor methods of production of greater capital intensiveness. The stimulus given to methods of greater capital intensiveness is shown in Table 16–16 by the effects on profits and the rate of profit of three different magnitudes of sales revenues. The largest magnitude of sales revenues, \$11,000, which appears in the upper portion of the table, in the row labeled “Annual Sales Revenues (1),” is accompanied by profits of \$2,000, \$3,000, and \$4,000 for methods A, B, and C respectively, and thus by corresponding rates of profit of 20 percent, 15 percent, and 13 $\frac{1}{3}$ percent respectively. These results appear lower in the table, in the respective rows “Annual Profits (1)” and “Annual Rate of Profit (1).” With sales revenues at \$11,000, method A, the least-capital-intensive method, is the relatively most profitable.

When sales revenues for the same quantity of product fall to \$10,000, the profits of methods A, B, and C, with their respective costs of \$9,000, \$8,000, and \$7,000, fall to \$1,000, \$2,000, and \$3,000, respectively. This results in the three methods of production now earning the same rate of profit on capital, given their respective capital requirements. These results are shown in the rows labeled “Annual Profits (2)” and “Annual Rate of Profit (2).”

When, finally, sales revenues fall to \$9,000, as shown in the row labeled “Annual Sales Revenues (3),” the profits of method A are totally eliminated. Method B continues to show a profit of \$1,000, which yields a rate of profit of 5 percent on the \$20,000 of capital which must be invested in that method. But method C continues to show a profit of \$2,000, which represents a rate of profit of 6 $\frac{2}{3}$ percent on the \$30,000 of capital which must be invested in it. By comparison method C, the most capital intensive of the three methods, is now favored. These results appear in the rows labeled “Annual Profits (3)” and “Annual Rate of Profit (3).”

Table 16-16
Capital Intensive Methods and the Rate of Profit

Method of Production:	A	B	C
Capital Required:	\$10,000	\$20,000	\$30,000
Annual Production Costs:	9,000	8,000	7,000
Annual Sales Revenues (1):	11,000	11,000	11,000
Annual Sales Revenues (2):	10,000	10,000	10,000
Annual Sales Revenues (3):	9,000	9,000	9,000
Annual Profits (1):	2,000	3,000	4,000
Annual Profits (2):	1,000	2,000	3,000
Annual Profits (3):	0	1,000	2,000
Annual Rate of Profit (1):	20%	15%	13.33%
Annual Rate of Profit (2):	10%	10%	10.00%
Annual Rate of Profit (3):	0	5%	6.67%

This outcome should in no way be thought paradoxical. What brings it about is the fact that the more-capital-intensive methods are the lower-cost methods. As sales revenues for a given quantity of the product fall, the only way to remain profitable is by achieving lower costs of production. The way to achieve that is by investing more capital.⁹⁴

As I have indicated, a lower rate of profit favors more capital intensiveness not only in cases in which more capital intensiveness achieves lower-cost methods of production, but also in cases in which more capital intensiveness achieves a better quality of products. An example which clearly brings out this principle is the case of thirty-year-old scotch versus eight-year-old scotch. Thirty-year-old scotch is a much higher-quality scotch than eight-year-old scotch. Its production also requires the use of substantially more capital per unit of output and is thus correspondingly more capital intensive. If thirty-year-old scotch is to be produced on a regular basis, then for every unit of scotch reaching the market in any particular year, there must be twenty-nine other units, age one through twenty-nine, in the hands of its producers. If eight-year-old scotch is to reach the market on a regular basis, there need be only seven other units—the units age one through seven—in the hands of its producers, for every unit that comes to the market in

any given year.

The rate of profit on capital invested is one of the determinants of the prices of goods. And its role is the more pronounced, the more time consuming and capital intensive the production of a product is, and also the higher is the rate of profit. If the rate of profit is 10 percent per year, then for every \$100 invested in a quantity of raw scotch, the price of eight-year-old scotch must provide \$214, for that is the sum required to yield a 10 percent annual rate of profit on \$100 compounded for eight years. By the same token, for every \$100 invested in a quantity of raw scotch, the price of thirty-year-old scotch must provide the vastly larger sum of \$1,745, because that is the sum required to yield a 10 percent annual rate of profit on \$100 compounded for thirty years.

Observe. In this case, with the rate of profit at 10 percent, the thirty-year-old scotch must sell for more than eight times the price of the eight-year-old scotch, so greatly does the 10 percent rate of profit influence its relative price. But now let us see what happens if the rate of profit were 5 percent instead of 10 percent. To yield a rate of profit of 5 percent compounded for eight years, the eight-year-old scotch would have to sell for \$148. To yield a 5 percent rate of profit compounded for thirty years, the thirty-year-old scotch would have to sell for

\$432. In this case, with the rate of profit at 5 percent, the thirty-year-old scotch need sell for only 2.9 times the price of the eight-year-old scotch, instead of more than 8 times the price of the eight-year-old scotch, which was the case when the rate of profit was 10 percent. The lower is the rate of profit, the smaller is the premium which must exist in the price of the older scotch. If the rate of profit were zero, the price of thirty or even one-hundred-year-old scotch would need to be no higher than the price of the eight-year-old scotch.

Now what is significant from the point of view of the present discussion, about the prices of the two scotches moving closer together as the rate of profit falls, is that this development is bound to favor the demand for the older, better-quality scotch. As the premium on this scotch falls, people will be able to give greater and greater consideration to its superior quality. As a result, the share of the market served by this more-capital-intensive product increases, and thus the need is created for the overall degree of capital intensiveness in this industry to go up.

This case illustrates the general principle that as the rate of profit falls, the premium in the prices of all higher-quality products whose production is relatively more time consuming diminishes, and thus the share of the market served by such products increases, with the result that a need is created for a higher overall degree of capital intensiveness in the economic system. Some further examples of the application of this principle are the comparative use of woods from trees of different growing times, the relative share of the market supplied with aged beef, and, in general, the share of the market supplied with products requiring the use of relatively more valuable raw materials further back in the production process or requiring the use of relatively more expensive plant and equipment in their production, particularly at

earlier stages in their production.

The principle here sheds further light on the effects of a fall in the rate of profit on the use of more-capital-intensive methods of production in general. For example, with a rate of profit of 10 percent per year, a machine which costs \$1,000 and lasts 10 years, must, if it is to be worthwhile, bring in each year the sum of \$150 in the sales revenue of the product it helps to produce. This sum reflects an annual depreciation charge of \$100 plus a 10 percent rate of return on the average capital outstanding in the machine over its life, which latter is one half of the initial capital invested, viz., \$500. Thus, over its ten-year life, the machine must bring in a revenue over its cost of \$500—i.e., 10 times (\$150-\$100). But if the rate of profit were 5 percent instead of 10 percent, then the machine would need to bring in each year only \$125, and thus, over its ten-year life, only \$250 in revenue over its cost. With the reduction in the premium in the revenue from the sale of the product that is required to make a machine pay, the value of the machinery employed in production necessarily tends to increase. And, of course, identically the same principle applies to the value of the buildings employed in production. Thus, the wider principle that capital intensiveness is favored as the rate of profit falls receives further confirmation.

In a very similar way, it can be shown that as the rate of profit falls, the growth of the more-capital-intensive industries in the economic system is favored relatively to the growth of the less-capital-intensive industries, with the result that once again a need is created for a higher overall degree of capital intensiveness in the economic system. This is shown in Table 16-17. There, Industry A, with a ratio of sales to capital of 10:1, is the least capital intensive. Industry B, with a ratio of sales to capital of 1:1, is more capital intensive. Industry C, with

Table 16-17
Capital Intensive Industries and the Rate of Profit

Industry:	A	B	C
Sales/Capital:	10	1	1/3
Profit/Sales:	1%	10%	30%
Profit/Capital:	10%	10%	10%
Sales/Capital:	10	1	1/3
Profit/Sales:	1/2%	5%	15%
Profit/Capital:	5%	5%	5%

a ratio of sales to capital of only 1:3, is the most capital intensive. (We can think of Industry A as representing supermarkets, which have an extremely rapid turnover of the portion of their capitals that is invested in inventories, and thus a very high overall ratio of sales to capital. Industry B can be taken as representing the automobile industry. And Industry C, finally, can be taken as representing the electric utility industry, almost all of whose capital is invested in power plants and wires underground, both with an extremely long life.)

The fact that these industries have such unequal rates of capital turnover (the sales to capital ratios) requires, of course, that they have correspondingly unequal profit margins—that is, profits as a percentage of sales—if they are all to earn the same rate of profit on capital invested.⁹⁵ Thus, in order for Industry A to earn a 10 percent rate of profit on capital invested, it requires a profit margin of only 1 percent. If it earns a profit of a mere 1 percent of sales, but its sales are 10 times its capital, it earns a 10 percent rate of profit on its capital. Industry B needs to earn a profit margin of 10 percent, if, with its 1:1 ratio of sales to capital, it is to earn a 10 percent rate of profit on its capital invested. And, of course, Industry C needs to earn profits on sales of fully 30 percent, if, with its 1:3 ratio of sales to capital, it is to earn a 10 percent rate of profit on its capital invested. All this is shown in the top half of Table 16–17.

The bottom half of Table 16–17 shows the profit margins that are required in the three industries if the rate of profit on capital invested is 5 percent instead of 10 percent. These lower profit margins are ½ percent, 5 percent, and 15 percent, respectively.

Now inasmuch as these lower profit margins are brought about by a fall in the selling prices of the products of the three industries, Table 16–17 implies that a decline in the rate of profit causes a relatively greater reduction in the prices of the products of more-capital-intensive industries than of less-capital-intensive industries. As the rate of profit falls from 10 percent to 5 percent, the price of the product of industry C falls by 15 percent, that of B by 5 percent, that of A by only ½ percent, for these are the extent of the price declines needed to achieve the respective reductions in profit margins. Because of this pattern of price reductions, the demand for the products of more-capital-intensive industries is favored, and therefore the need for capital intensiveness in the economic system is once more increased.

Thus, to summarize, a lower rate of profit on capital invested encourages greater capital intensiveness in the economic system by reducing the cost savings that more-capital-intensive investments must achieve relative to the additional capital required. This was shown in the example of the railroad tunnel. It is also accompanied by

a more rapid wiping out of the profit margins of higher-cost, less-capital-intensive methods of production than of the profit margins of lower-cost, more-capital-intensive methods of production, with the result that the more-capital-intensive methods are rendered the comparatively more profitable. This was shown in the example of the three methods of producing the same quantity of the same product. In addition, a lower rate of profit reduces the premiums in price or in revenue that more-capital-intensive products, more capital-intensive-methods of production, and more-capital-intensive industries must bear relative to less-capital-intensive products, methods of production, and industries. This was shown in the example of scotch of different ages, the example of the additional revenue required to make the use of machinery or buildings pay, and, finally, the example of the industries of different degrees of capital intensiveness. In all these ways, a lower rate of profit favors a higher degree of capital intensiveness.

If this principle is understood, then it should now be possible to understand the claim made earlier that if for any reason the rate of profit is wiped out or made unduly low, the basis exists for an automatic restoration of profitability through net investment. All one has to realize is that when confronted with an unduly low rate of profit, businessmen are motivated to divert outlays for factors of production from some of their present lines to lines representing a higher degree of capital intensiveness, because, by comparison, these will appear as more profitable lines. Thus, if most businesses are earning little or no profit with the employment of their present amounts of capital, then what they need is more capital, in order to reduce their annual costs of production and/or to increase their sales revenues by virtue of having improved products to sell. In this situation what will happen is a withdrawal of capital from some of its present lines of employment and diversion to more-capital-intensive lines, as representing a more profitable use of existing capital. For example, unprofitable retail businesses will withdraw some of their capital from the retailing trade and make it available in the loan market, where it will be borrowed and used for the construction of things like additional railway tunnels. At the same time, some of the retailers will merge with one another, in order to carry on business more capital intensively and more economically. Such retailers will themselves probably seek additional capital.

What is present here is a shifting of productive expenditures from points less remote from showing up as costs of production to points more remote from showing up as costs of production, with the result that for a more-or-less-extended period of time a reduction takes place in the costs business subtracts both from its outlays for

factors of production and from its sales revenues.⁹⁶ This reduction in costs deducted is the reflection of a larger proportion of the output of the economic system being retained within business firms, instead of being turned over to customers in the sale of inventories or lost through depreciation or expensed expenditures. On the one side, it represents the accumulation of assets, which is a hallmark of net investment and the growth in capital intensiveness. On the other side, it represents an increase in profitability. Thus, the effect of the impetus toward additional capital intensiveness is a restoration of business profitability on the strength of the additional net investment entailed.

Of course, as my discussion of the sources of profit has shown, the restoration of profitability achieved by additional net investment is not confined to the existence of that net investment itself. The net investment spring presently under discussion tends to activate the other springs to profitability as well. This is because the higher degree of capital intensiveness that is brought about operates to increase production and thus, in the long run, and indirectly, the rate of increase in the supply of a commodity money.⁹⁷ The net investment spring also activates the net consumption spring in that the elimination of negative net investment immediately allows net consumption to generate profits equal to itself.⁹⁸ Moreover, in the conditions of recovery from a depression, the accompaniment of the net investment spring is a reduction in the demand for money for holding, which, in the short run, further adds to net investment and the nominal rate of profit, by raising productive expenditure and sales revenues relative to costs.

Wage Rate Rigidities and Blockage of the Springs

Given the existence of the various springs to profitability that have now been explained, the question arises of why the economic system does not in fact always spring back to profitability in the midst of a depression. One part of the answer, of course, is that the process of financial contraction and deflation must first come to an end, so that the financial losses inherent in that process can be avoided. Another essential part of the answer, which is necessary to limit the extent of the financial contraction and deflation, is that there must be a sufficient fall in wage rates. Before the critical net-investment spring can be activated, wage rates must fall to the level required for full employment in the face of the existing demand for money and quantity of money—a demand for money that is greater than it was before the depression, and a quantity of money that is very possibly smaller than it was before the onset of the depression. The demand for money in a depression is greater both because it has been deprived of the stimulus to spending

created by inflation and credit expansion, and because of the existence of the process of financial contraction itself, especially when accompanied by bank failures under a fractional reserve banking system, which serve to reduce the quantity of money.

As I explained in Chapter 13, the failure of wage rates to fall to the full-employment point causes a postponement of investment expenditures, and thus a wiping out of net investment and profitability, indeed, causes negative net investment and losses.⁹⁹ The operation of the springs to profitability comes into play only when wage rates reach the new, lower level that has become necessary for full employment, thereby eliminating the threat that present investments will be rendered unprofitable by substantial wage-rate reductions in the year or two ahead. At that point, the operation of the springs guarantees the restoration of net investment and profitability.

Capital Intensiveness and the Monetary Component in the Rate of Profit

Preceding analysis has shown that there is always need for greater capital intensiveness, that if ever the rate of profit disappears or becomes unduly low, the movement toward greater capital intensiveness acts to raise the rate of profit back up, and that the reestablished rate of profit then limits the move toward any further increase in the degree of capital intensiveness. A question now arises concerning specifically *the monetary component* that is added to the rate of profit by virtue of the more rapid increase in the supply of commodity money that a higher degree of capital intensiveness brings about. Namely, does the monetary component in the rate of profit operate to reverse the increase in the degree of capital intensiveness that brought it about in the first place, as would a rise in the rate of net consumption or a rise in the rate of net investment brought about by carrying on the process of capital intensification too rapidly?

There is some important evidence for believing that the rise in the rate of profit caused by the monetary component does not have this effect, that it does not react back, as it were, and undermine the higher capital intensiveness on which it rests. This is because there is reason for believing that the relationship between capital intensiveness and the rate of profit pertains exclusively to *that portion of the rate of profit that does not reflect the increase in the quantity of money.*

The case of the thirty-year-old scotch versus the eight-year-old scotch can be used to perform an intellectual experiment that will demonstrate this point. We have seen how a fall in the rate of profit from 10 percent to 5 percent encouraged capital intensiveness by causing the price of the older scotch to fall to a greater extent than that of the younger scotch and thus to encourage the

purchase of the older, more-capital-intensive scotch at the expense of the purchase of the younger, less-capital-intensive scotch. Now what we will do is see if this encouragement to greater capital intensiveness is reversed by virtue of a more rapid rate of increase in the quantity of money that restores the rate of profit to 10 percent.

We saw that the fall in the rate of profit from 10 percent to 5 percent caused the price of the thirty-year-old scotch to fall from \$1,745 to \$432, while it caused the price of the eight-year-old scotch to fall from \$214 to \$148. This implied a fall in the ratio of the price of the older to the younger scotch from over 8:1 ($\$1,745/\214) to less than 3:1 ($\$432/\148). The test of whether or not an addition to the rate of profit by virtue of an increase in the quantity of money undermines the higher capital intensiveness on which the increase in the quantity of money rests will be whether or not the change in the relative prices of the two scotches is reversed by the more rapid rate of increase in the quantity of money.

For the sake of simplicity, we can assume that a more rapid rate of increase in the quantity of money takes place that is sufficient fully to restore the rate of profit, namely, to raise it all the way back up to 10 percent from the 5 percent to which it fell on the basis of a reduction in the rate of net consumption. If in raising the rate of profit back up to 10 percent, the increase in the quantity of money raises the ratio of the price of the thirty-year-old scotch to the price of the eight-year-old scotch back to 8:1, then we will have to conclude that the rise in the rate of profit caused by the more rapid increase in the quantity of money that is attributable to greater capital intensiveness does, indeed, work against the capital intensiveness on which it rests. If, on the other hand, we find that the rise in the rate of profit attributable to the more rapid growth in the quantity of money is not accompanied by any rise in the ratio of the price of the thirty-year-old scotch to the price of the eight-year-old scotch, then we must conclude that this kind of rise in the rate of profit does not work against capital intensiveness.

Well, what do we find? We find that if the quantity of money and volume of spending in the economic system now begin to increase at an annual rate of 5 percent (which is what will operate to raise the rate of profit from 5 percent to approximately 10 percent), the price of thirty-year-old scotch tends to be elevated by a factor of 1.05^{30} , which is an increase of 4.32 times.¹⁰⁰ Thus, instead of being \$432, it will tend to be $\$432 \times 4.32$, or \$1,867. By the same token, the price of eight-year-old scotch will tend, in eight years, to be elevated from \$148 to $\$148 \times 1.05^8$, or to \$218. On this basis, it may appear that the old 8:1 ratio is restored.

But this conclusion would be premature. Because

what we must realize is that the more rapid rate of increase in the quantity of money and rise in the volume of spending does not stop its influence on the price of the eight-year-old scotch after eight years. It goes on influencing the price of the eight-year-old scotch *year after year*. In fact, it influences the price of eight-year-old scotch that will be available in thirty years fully as much as it influences the price of the thirty-year-old scotch that will be available in thirty years. The price of eight-year-old scotch to be available thirty years from now will also tend to be increased by a factor of 1.05^{30} —that is, by exactly the same factor as the price of the thirty-year-old scotch. Eight-year-old scotch, thirty years from now, will tend to sell for $\$148 \times 4.32$, or \$639. The thirty year old scotch, at \$1,867, is not eight times as expensive, but less than 3 times as expensive ($\$1,867/\639), just as it was with a rate of return of only 5 percent.

What is decisive in bringing about this result is the fact that the more rapid rate of increase in the quantity of money and volume of spending go on acting on the price of the younger scotch year after year. If, on the other hand, the rise in the rate of profit had been the result of a rise in the rate of net consumption, the price of eight-year-old scotch would have been increased, but the price of eight-year-old scotch thirty years from now would not have tended to be any higher than the price of eight-year-old scotch eight years from now. A rise in the rate of profit attributable to a rise in the rate of net consumption would have raised the prices of the eight-year-old and thirty-year-old scotches unequally, for it would have operated on the price of the one for just eight years and on the price of the other for thirty years.¹⁰¹ But a rise in the rate of profit attributable to a more rapid rate of increase in the quantity of money is accompanied by equivalent percentage increases in both prices, because the more rapid increase in the quantity of money goes on affecting both prices year after year.

Thus, this case shows that the rise in the rate of profit that results from greater capital intensiveness bringing about a more rapid rate of increase in the supply of commodity money does not react back and undermine the higher degree of capital intensiveness. The case must be understood as demonstrating this fact as a general proposition, because every instance of greater or lesser degrees of capital intensiveness represents merely the outlay of sums of money for longer or shorter times in advance of the sale of the product to whose production the sums of money contribute. In other words, every instance of different degrees of capital intensiveness can be conceived of as the scotch case or combinations of the scotch case.

This conclusion can be readily confirmed in such cases as that of the railway tunnel. In cases of this kind,

the increase in the quantity of money and volume of spending would operate to increase the annual savings in operating costs to the same extent as they operated to increase the nominal rate of profit, for they would operate to make the wages and prices that constituted the operating costs higher each year by the same percentage as they added to the rate of profit. Thus, in such cases, the higher rate of profit brought about by the increase in the quantity of money would not serve to discourage greater capital intensiveness if the greater capital intensiveness were profitable otherwise.

Nevertheless, I have not yet been able satisfactorily to verify this finding in terms of examples of different methods of production capable of producing the same quantity of a given product, and of industries with different capital turnover ratios. In these cases, looking simply at the examples themselves, it appears that a rise in the rate of profit caused by the addition of a monetary component *does* operate to discourage capital intensiveness. This is because what is present is a rise in sales revenues relative to costs and thus a favoring of less-capital-intensive methods. In view of the fact that, independently of this, the increase in the quantity of money can be shown to have a substantial effect on the rate of net consumption, and thereby without question to undermine capital intensiveness, it is clearly best if the rate of increase in the quantity of money is moderate, as it would be under a 100-percent-reserve gold standard.¹⁰²

Capital Intensiveness Under Rapid Obsolescence

Inasmuch as I have just dealt with the question of the possible reactive effect of the increase in the quantity of money caused by a higher degree of capital intensiveness, on the degree of capital intensiveness, this is the logical place to deal with the possible reactive effect of the economic progress caused by a higher degree of capital intensiveness, on the degree of capital intensiveness. Namely, does it react back and reduce the degree of capital intensiveness?

This question arises because in the context of a rapidly progressing economy, the rate of obsolescence of machines and factories increases, necessitating more rapid depreciation.¹⁰³ It should not be thought, however, that this implies any tendency toward a diminution in the degree of capital intensiveness in the economic system. For reasons both already explained and yet to be explained, the rate of economic progress is not only positively related to the degree of capital intensiveness, but, if anything, the strength of this relationship is increased by the more rapid obsolescence that is caused by economic progress.

This is because the effect of such obsolescence is to require that a larger proportion of productive expenditure

take the form of a demand for machinery and factory construction rather than a demand for labor. This is illustrated by the fact that if the average machine in the economic system can be in service for, say, twenty years, then, on average, for every twenty workers using a machine, only one machine needs to be produced in any given year. But if because of more rapid obsolescence, the average machine can be in service for only ten years, then for every twenty workers using a machine, an average of *two* machines must be produced in any given year. The effect of such a change is to increase the demand for capital goods at the expense of the demand for labor and thus at the expense of the demand for consumers' goods, which comes mainly from wage earners. Thus, the result is a rise in the degree of capital intensiveness as measured by the ratio of capital to the demand for consumers' goods or to wage payments.

This discussion, incidentally, implies the need for a modification in the measurement of capital intensiveness. Up to now, I have described capital intensiveness equivalently in terms of the ratio of capital to consumption expenditure, to wage payments, and to sales revenues. In actuality, the ratio of capital to consumption expenditure or to wage payments is a better measure of capital intensiveness than the ratio of capital to sales revenues. True enough, a rise in the ratio of capital to sales revenues does constitute an increase in the degree of capital intensiveness. But the present discussion calls attention to the fact that the degree of capital intensiveness can increase even though the ratio of capital to sales revenues remains the same or even declines somewhat. Capital intensiveness increases when a larger proportion of sales revenues is for capital goods and a smaller proportion is for consumers' goods. This change is reflected in the ratio of capital to receipts from the sale of consumers' goods, but it is not reflected in the ratio of capital to sales revenues as such. Thus, in the above example of the annual purchase of two machines with a ten-year life taking the place of the annual purchase of one machine with a twenty-year life, the ratio of net plant to sales revenues declines slightly, but the ratio of net plant to receipts from the sale of consumers' goods rises, and thus capital intensiveness increases.

This conclusion is illustrated by taking the initial amount of annual expenditure for plant and equipment as 100 monetary units. Under this assumption, with annual depreciation at the rate of 5 percent, net plant comes to equal 2,000 monetary units of gross plant minus 1,050 monetary units of accumulated depreciation, that is, 950. (Accumulated depreciation amounts to 1,050 monetary units after 20 years because that is the sum of 20 terms starting with 5 and incrementing by 5 each year until, in *Year 20*, an annual total of 100 of depreciation

is reached.) If total sales revenues are 1,000 and receipts from the sale of consumers' goods are 500, then the ratio of capital in the form of net plant to sales revenues is .95 ($950/1,000$) and the ratio of capital in the form of net plant to receipts from the sale of consumers' goods is 1.9 ($950/500$). Now, in the face of economic progress and more rapid obsolescence, annual expenditure for plant and equipment rises to 200. This, together with the reduction in the depreciable life of the plant and equipment to 10 years, results in net plant coming to equal 900. (This is because gross plant comes to equal 2,000, as before, but accumulated depreciation comes to equal 1,100 instead of 1,050. The figure of 1,100 is the sum of 10 terms starting with 20 of annual depreciation and incrementing by 20 until 200 of annual depreciation is reached in *Year 10*.) In this case, the ratio of net plant to sales revenues falls to .9 from .95 ($900/1,000$). But because the rise of 100 in annual demand for plant and equipment is at the expense of a fall of 100 in the annual demand for consumers' goods, capital intensiveness as measured by the ratio of capital to consumption, rises from 1.9 ($950/500$) to 2.25 ($900/400$).

Such an increase in the degree of capital intensiveness occurs in every case in which a higher degree of capital intensiveness results in more rapid obsolescence of plant and equipment and thus in a rise in the demand for capital goods at the expense of the demand for labor.

Accordingly, it is clear that the effect of a higher degree of capital intensiveness and the more-rapid economic progress and consequent more-rapid obsolescence of plant and equipment that it causes is not to react back and reduce the degree of capital intensiveness.

PART B

THE NET-CONSUMPTION/NET-INVESTMENT THEORY AND ALTERNATIVE THEORIES

In this part, I present a critical analysis of the major alternative theories of the rate of profit and interest, namely, the productivity theory and the time-preference theory. I also trace essential roots of the net-consumption theory to the writings of Ricardo, and examine a previous very brief and unsatisfactory exposition of the combined net-consumption/net-investment theory put forward earlier in this century by Michael Kalecki and then taken up Joan Robinson.

Apart from the Marxian exploitation theory, which I refuted in Chapter 11, the productivity and time preference theories, or, indeed, as is most often the case, the two taken together in combination, are the most popular

theories of the rate of profit and interest. A leading purpose of this part is to show that to whatever extent the productivity of capital and time preference actually do determine the rate of return on capital, they do so exclusively by way of their respective influence on the rate of net investment and the rate of net consumption, and that apart from these connections they have absolutely no influence on the rate of return.

1. Exposition and Critique of the Productivity Theory in Its Traditional Form

The productivity theory can be understood in terms of a famous example developed by Roscher and then repeated by Böhm-Bawerk in preparation for his critique of the doctrine. Böhm-Bawerk quotes Roscher as follows:

"Let us imagine a nation of fisher[men], without private ownership or capital, dwelling naked in caves, and living on fish caught by hand in pools left by the ebbing tide. All the workers here may be considered equal, and each man is presumed to catch and eat 3 fish per day. But now one prudent man limits his consumption to 2 fish per day for 100 days, lays up in this way a stock of 100 fish, and makes use of this stock to enable him to apply his whole labor power for 50 days to the making of a boat and net. With the aid of this capital he catches 30 fish a day from that time on."¹⁰⁴

If we assume, as does Böhm-Bawerk, that the boat and net last for 100 days, then we have the following situation. Each day's use of the boat and net enables the fisherman using it to catch 27 more fish than he otherwise would have, or 2,700 additional fish in all. In the terminology of the contemporary supporters of the productivity theory, this is the marginal gross product of the capital constituted by the boat and net—it is what the boat and net add to the catch of the fisherman. The marginal net product of this capital is found by subtracting the cost of constructing the boat and net, which is the value of the 50 days of labor required to construct them. The value of this labor, according to the supporters of the productivity theory, is 3 fish per day, or 150 fish in total, for that is the product that must be forgone in order to construct the boat and net. (Obviously, the supporters of the productivity doctrine also support the opportunity-cost doctrine.) The marginal net product of the boat and net thus appears as 2,550 fish—the 2,700-fish-marginal-gross product of the boat and net minus the opportunity cost of 150 fish forgone in order to construct the boat and net.

The implied rate of return on capital here is the 2,550 fish of marginal net product divided by the amount of fish representing the average value of the capital invested, which is 75 fish.¹⁰⁵ The resulting rate of return is 3,400 percent. And since this rate of return is earned

over a period of just 150 days and thus could be earned more than twice in a year, the implied annual rate of return is over 2 times that, i.e., more than 6,800 percent.

It should be realized, of course, that the productivity theory by no means necessarily implies the existence of high rates of return. The above rates of return result merely from the particular assumptions that happen to have been used in the example. The supporters of the productivity theory are willing to concede the possible existence of very high rates of return in such primitive conditions, but argue that the law of diminishing returns quickly sets in, which operates to reduce marginal gross and net products relative to successive equal increments of capital invested. Indeed, based on the law of diminishing returns, the productivity theory implies a tendency toward a constantly falling rate of return on capital invested, as additional capital is accumulated. The major factor offsetting this tendency, in its view, is technological progress, which allegedly operates to keep up the rate of profit by creating new investment opportunities.

All of these views can be found in the textbook of Samuelson and Nordhaus, whose exposition is typical and, at the same time, even uses the very example of the fish and boat and net:

... investing in capital goods involves indirect or round-about production. Instead of catching fish with our hands, we find it ultimately more worthwhile first to build nets and boats—and then to use the nets and boats to catch many more fish than we could by hand.

Put differently, we frequently forgo present consumption to increase future consumption. Fewer fish caught today frees up labor for making nets to catch many more fish tomorrow. Society thus invests, or abstains from present consumption, and by waiting obtains a yield or return on that investment. *In the most general sense, this yield—more future consumption in return for forgone present consumption—is the return on capital.*¹⁰⁶

These passages clearly express the productivity theory's conception of the rate of profit as representing the physical net productivity of capital. A few paragraphs later, they are followed by the passages I quoted back in Chapter 13, which express equally clearly the productivity theory's view of the influence of the law of diminishing returns and technological progress on the rate of profit.¹⁰⁷

When I quoted the passages in Chapter 13, I dealt with the productivity theory's errors with respect to technological progress. I showed technological progress to be a source of the supply of capital goods, not of "the demand for capital," and to be fundamentally neutral with respect to the average rate of profit. That is, I showed that technological progress neither raises the average rate of profit (except to the extent of contributing to the more rapid increase in the quantity of a commodity

money) nor lowers it by virtue of being the cause of alleged deflation, i.e., of falling prices. Later, I showed that in the absence of technological progress, the effect of the operation of the law of diminishing returns would be to reduce the rate of capital accumulation and economic progress, both of which would peter out in the sustained absence of technological progress.¹⁰⁸ This, rather than any reduction in the rate of profit, is the actual effect of the operation of the law of diminishing returns insofar as it is not offset by technological progress. In the next chapter, I will completely lay to rest the doctrine that capital accumulation causes a tendency toward a falling rate of profit.¹⁰⁹

There are further difficulties with the productivity theory in its traditional form. Among them is the fact that it rests on the acceptance of the doctrine of opportunity cost, as is apparent from the example of the boat and net. Needless to say, I have also already exposed the errors of this doctrine.¹¹⁰ Furthermore, even if the opportunity-cost doctrine were free of error, the productivity theory must break down in every case in which the larger quantity of the consumers' good produced is physically different than the consumers' goods forgone in order to produce it. For example, how would one calculate the rate of return if what had to be forgone in order to construct the boat and net were, say, 150 loaves of bread instead of 150 fish? How does one calculate the difference between 2,700 fish and 150 loaves of bread?

This last difficulty implies that the very concept of a marginal net *physical* productivity of capital goods is simply illegitimate when applied in the context of individual firms and industries, whose output in a division-of-labor society is always physically very different than their inputs. The only legitimate concept of marginal productivity in this context is the one I have employed, which refers to the reductions in money costs and/or increases in sales revenues to be achieved by the employment of additional capital—additional capital, it must be stressed, not in the sense of additional physical capital goods, but in the sense of a monetary value both of the capital goods purchased *and of the producers' labor employed*.

In the context of a division-of-labor society, the concept of a marginal net *physical* productivity of capital goods is legitimate only at the level of the economic system as a whole. The economy as a whole productively consumes capital goods which in turn makes possible the production of an output that replaces the capital goods consumed and more. From the perspective of the economic system as a whole, it is legitimate to view the capital goods consumed and the product produced as homogenous—at the very abstract level of units of wealth consumed and produced. Thus, at this level of abstrac-

tion, one may properly think in terms of a net physical productivity of capital goods.

It is at this level of abstraction that we will apply and analyze the example offered by Roscher and Böhm-Bawerk concerning the fishermen. When we do so, it will become obvious that the productivity theory in the form in which it is presently expounded—namely, as an attempt to explain the rate of profit on the basis of a net physical surplus in production—simply does not explain what it is absolutely essential for a valid theory of the rate of profit to explain. This, of course, is the answer to the question of just how an economy-wide surplus of *money sales revenues over money costs of production* comes into existence and is maintained. The existence of such a surplus is indispensable to the existence of a positive average rate of return on capital in the economic system as a whole. Without it, there cannot be a rate of profit or rate of return.

The fact that an individual fisherman or, indeed, everyone in the economic system—which is what all the fisherman taken together in the example are supposed to represent—adopts more productive methods of production and thus turns out a larger physical output does not in fact imply any addition whatever to the total of sales revenues in the economic system or any diminution in aggregate costs of production in the economic system. It thus implies nothing whatever about the average rate of profit in terms of money.

To understand this fact, let us take the case of the fishermen as the basis of an example in terms of money. Let us imagine that there is a society of 1 million fishermen organized into 1 million fishing enterprises, which initially produce 3 million fish a day, which they sell for \$3 million, or at a price of \$1 per fish. In other words, we take 3 million fish to represent the total physical product of the economic system and \$3 million to represent the aggregate monetary demand for that product.

Having made these assumptions, still another problem arises for the productivity theory. Namely, it turns out that in such primitive conditions, in which there are as yet no capital goods and in which, therefore, the manual workers who gather the fish can be presumed simply to produce and sell their own products and not to act as capitalists, the full sales proceeds of the fishermen are profits! This, of course, follows from the fact that, not acting as capitalists, they do not make productive expenditures and therefore have no money costs to deduct from their sales revenues.¹¹¹ It also turns out that the rate of return on capital in these conditions is infinite! This last point follows because the fishermen's profit would be earned on a capital invested of zero. This is because, in the absence of productive expenditure, there can be no capital in terms of money, as well as no costs in terms of

money.¹¹² These facts represent a serious difficulty for the productivity theory, because the theory claims to be an explanation of the *genesis* of profit and the rate of return, and here they are in existence *prior* to any capital or productivity of capital, with profit at a height in relation both to sales revenues and to capital that it will never afterwards achieve.

But we can put this difficulty aside and simply imagine that each of these fishermen is paid a wage of, say, \$2.50 per day by some kind of external fishing enterprise. This assumption enables us to zero in on the central difficulty of the productivity theory in the context of an economic system that uses money and has an existing economic degree of capitalism—of buying for the sake of subsequently selling. For now we are in a position to see clearly just why the productivity theory in its present form, is simply unable to explain the determination of the general rate of profit.

What we have is the following situation. Because of the use of a boat and net, one individual fisherman produces 30 fish per day instead of 3 fish per day. All the rest of the fisherman continue as before. Thus, the output of the economic system as a whole rises from 3 million fish to 3 million and 27 fish per day. Given the same supply of money in the economic system and the same demand for money for holding, total spending to buy products (in this case represented exclusively by fish) remains \$3 million. Thus, total sales revenues in the economic system remain \$3 million. As a result, the price of fish declines from \$1 per fish to \$1 times the fraction formed by dividing 3 million by 3 million and 27.

In these circumstances, our individual fisherman with the tenfold increase in his output takes in almost ten times the sales revenue. The monetary profit of *his* enterprise is thus very greatly increased. But by the same token, the monetary profits of all the other fishing enterprises in the economic system taken together are equivalently decreased. Collectively, they take in as much less in sales revenue as he takes in more. And thus their profits are as much reduced as his are increased. In the economy as a whole, total sales revenues remain at \$3 million and total costs of production remain at \$2.5 million (1 million fishing enterprises, each with a wage cost of \$2.50). Thus, total profits in the economic system remain at \$500,000.

Nothing is changed as far as the average rate of profit is concerned if all the fishing enterprises adopt the use of boats and nets and collectively turn out 30 million fish per day instead of 3 million fish per day. So long as the quantity of money and the demand for money for holding remain the same, aggregate sales revenues remain the same. So long as the average fisherman is paid a wage of \$2.50 per day, aggregate costs remain the same. And thus

aggregate profits remain the same—once again, at \$500,000. Whatever the money value of the capital invested in the economic system, the average rate of return on capital remains at the figure formed by dividing that amount of capital into the \$500,000 of aggregate profit. All that is different is that, because of their tenfold increase in supply in the face of the same aggregate demand, fish now sell for an average price of 10 cents instead of \$1. To the extent that nominal profits exist—on some other basis than that of the productivity theory, of course—real profits may be said to be increased by a factor of 10 by virtue of the 90 percent fall in prices. Real wages too are increased by this multiple. But the nominal amount and rate of profit would be unchanged, and nominal wages would be unchanged.

There are only two ways that the adoption of the more productive methods of production symbolized by the boats and nets would be capable of affecting the general monetary rate of return on capital. One would be the extent to which the more productive methods could be applied to the mining of the precious metals under a system of gold and silver commodity money. This would result in a more rapidly growing quantity of money and volume of spending in the economic system, and thus in more rapidly rising aggregate sales revenues, which last would raise the rate of return in the ways explained earlier in this chapter.¹¹³ The other connection to the rate of return would be the extent to which the adoption of the more productive methods entailed net investment apart from increases in the quantity of money.

In the original example of the fisherman, it was assumed that 100 fish were saved up and that labor was then temporarily withdrawn from catching fish and devoted to constructing a boat and net instead, while the worker lived off of his accumulated stock of fish. That element of the example can be translated into monetary terms that have a bearing on the rate of return. Thus, let us imagine that for a time, the million fishing enterprises reduce their production of fish from 3 million per day to 2 million per day. For 150 days, they devote one-third of their labor to the construction of boats and nets (this would be equivalent to devoting their full labor for 50 days, as assumed in the original example). In these 150 days, aggregate sales revenues continue at \$3 million per day, as before. But aggregate costs *fall from \$2.5 million, to only two-thirds of that amount, i.e., to \$1.67 million.* The fall in aggregate costs takes place because the value of the labor going into the construction of the boats and nets is not charged against sales revenues, but is debited—added—to the value of the boats and nets under construction. In other words, there is a rise in aggregate profit and the average rate of profit, insofar as net investment takes place in connection with the adoption of the

more productive methods of production. Apart from the increase in the quantity of money, this is the only way that the adoption of more productive methods of production can be associated with the emergence of an average rate of return on capital in the economic system as a whole. In such cases, it is clear, what raises the rate of return is not the use of the more productive methods, but only such net investment as might take place in making possible their adoption.

Of course, in the context of an invariable money, the adoption of more productive methods of production made possible by a greater supply of capital goods would normally not entail any net investment in monetary terms, nor, therefore, any contribution to aggregate profit. The larger supply of capital goods would usually be the result of the greater production of capital goods that was part of the larger overall production made possible by a preceding increase in the supply of capital goods. As we have seen, this process of capital accumulation continuing indefinitely without need for further increases in the degree of capital intensiveness in the relative-value sense—which would be the necessary result of net investment in the context of an invariable money—is made possible by virtue of technological progress.¹¹⁴ Thus, under a system of invariable money, while more productive methods of production can be associated with a contribution to the rate of profit, by way of the accumulation of capital necessary to adopt them, as a rule even this association will not be present.

To be sure, in reality, the adoption of the more productive methods of production that an increasing supply of capital goods makes possible is normally accompanied by net investment in monetary terms and a corresponding contribution to aggregate profit. This is in the context of an economic system with an increasing quantity of money. But here too, it is not the adoption of the more productive methods of production, nor even the accumulation of capital required to undertake them, that is responsible for any contribution to the rate of profit, but, this time, the increase in the quantity of money and volume of spending that accompany the capital accumulation and adoption of more productive methods of production.

The truth is that apart from the increase in the quantity of money that it may contribute to, the marginal productivity of capital simply has no bearing on the rate of profit except insofar as it is a cause of net investment in a context in which it results in capital intensification in the relative-value sense. Indeed, the general marginal net productivity of *physical capital goods*, when conceived in terms of abstract units of wealth, such as has been the practice of this book, is almost certainly far higher than

the average rate of profit. Thus, for example, ever since the analysis of capital accumulation in Chapter 14, I have consistently assumed that the productive consumption of each unit K of capital goods results in the production of an output equivalent to $2K$ of capital goods. This implies a general, economy-wide constant marginal net physical productivity of capital goods of 100 percent. Yet the rate of profit in my examples was never even remotely this high. As we saw earlier in this chapter, when 500 monetary units were expended to buy IK of capital goods, and the resulting output of IK plus IC (which was equivalent to $2K$ of capital goods in terms of the physical wealth it represented) was sold for 1,000 monetary units, the rate of profit was only 11.11 percent, not 100 percent. This was because, first, 300 in wage costs had to be subtracted from the 1,000 of sales revenues, along with 500 of cost on account of capital goods. And then the 200 which remained for profit had to be divided by a capital of 1,800.

We are in a position to see also that profits differ from the general marginal net physical productivity of capital goods by virtue of the difference between increases in production and increases in sales revenues. In the conditions of an invariable money, there are no increases in aggregate sales revenues, no matter how much the general marginal net physical productivity of capital goods may increase. Indeed, we have already seen this just a few paragraphs ago in the demonstration that a tenfold increase in fish production accompanying an extremely high marginal net physical productivity in terms of fish, would not imply any addition to the amount or rate of profit in the conditions of an invariable money. The tenfold supply of fish, we saw, was accompanied by an unchanged aggregate demand and thus unchanged aggregate sales revenues. In the circumstances, all that occurred was a 90 percent reduction in the price of fish, and absolutely no increase in aggregate profits in terms of money.

We can see the same phenomenon in terms of the case of IK of capital goods and IL of labor, by assuming that instead of producing an output of IK and IC , they produce twice the output, namely, an output of $2K$ and $2C$. Under an invariable money, the sales revenues brought in by this doubled output would still be just 1,000 monetary units. And thus with the same expenditure of 800 monetary units for the factors of production, the amount of profit would remain 200 monetary units, and the rate of profit, 11.11 percent. This would be so even though the general marginal net physical productivity of capital goods had risen from 100 percent to 300 percent, based on the use of IK of capital goods to produce an output equivalent to $4K$ of capital goods instead of equivalent merely to $2K$ of capital goods. The effect of the higher

general marginal net physical productivity of capital goods would simply be an increase in output resulting in a fall in prices. The additional 200 percent of general marginal net physical productivity would have no ability to add to profits. It would add to production and reduce prices, but add nothing whatever to monetary profits.

When the concept of the marginal net physical productivity of capital goods is viewed in the light of my analysis of capital accumulation, it becomes clear that while it is not a cause of the rate of profit, it *is* a cause of the rate of physical capital accumulation and economic progress, or at least of the determination of the height of the relative demand for capital goods that is necessary to achieve physical capital accumulation and economic progress. Taken in the context of the economic system as a whole, as it should be, the concept of the marginal net physical productivity of capital goods is simply what I have all along been referring to as the productivity of capital goods, but taken net of the capital goods used up in production. Seen in this light, its true significance relates to the ability of the economic system to produce and to accumulate capital goods, not to the rate of profit. It determines how much can be produced from any given quantity of capital goods—such as IK —in terms not only of consumers' goods but also of further capital goods, and thus what proportion of output must be in the form of capital goods in order to make possible the replacement of the capital goods used up in production.

In summary, when applied in its only proper context, which is at the level of the economic system as a whole, the productivity theory rests on two central errors: First, it equivocates between capital and capital goods, thereby failing to see that wages are paid out of capital. This leads it to understate the cost of production by a failure to consider that portion of the capital used up which is constituted by wage payments, and thus to confuse a percentage of the cost of capital goods with a percentage of total cost and of capital as well. This was present in its implication that the rate of profit should be 100 percent in conditions in which IK of capital goods produces an output equivalent to $2K$ of capital goods, when in fact the rate of profit was only 11.11 percent. (Of course, the fact that the rate of profit was even as high as this cannot be explained by the productivity theory, but only by the existence of net consumption or, in a different context, by the existence of net investment along with net consumption.)

Second, the productivity theory ignores the relationship of net productivity to product prices. This enables it to proceed as though a gross physical product in excess of the quantity represented by the capital goods in question constitutes a larger value magnitude to the same extent. This was present in its implication that the rate of

profit should be 300 percent in conditions in which $1K$ of capital goods produces an output equivalent to $4K$ of capital goods. Here it overlooked the fact that nothing is automatically present to increase the magnitude of sales revenues as the magnitude of net productivity increases, and that if no such thing is present, the effect is simply a fall in prices, not an addition to profits. Of course, to the extent that such a factor is present, namely, a more rapid increase in the quantity of money and volume of spending, then it is this factor—the increase in money and spending—that must be regarded as the source of the additional profit, not the increase in physical net productivity. Indeed, this criticism is applicable to the productivity theory in every context, inasmuch as the productivity theory attributes the existence of profit as such to an increase in production achieved by the employment of capital goods.

2. Exposition and Critique of the Time-Preference Theory in Its Traditional Form

The time-preference theory in its traditional form seeks to explain the rate of return on capital in the following way. Other things being equal, it argues, people attach greater importance to the satisfaction of their wants in the present than in the future, and in the nearer future rather than in the more remote future. On this basis, the time-preference theory claims, they attach a higher valuation to goods available in the present rather than in the future, and in the nearer future rather than in the more remote future, because goods derive their value from the importance of the wants they serve, and are more highly valued to the degree that the wants they serve are more important. Thus, in the words of Böhm-Bawerk, people value “present goods” more highly than “future goods” of the same kind and quantity.¹¹⁵ For example, they value an apple or an automobile today more highly than an apple or an automobile not to be available to them until a year from now.

This preference for present goods over future goods supposedly enters into the valuation of the factors of production. The totality of the factors of production required to produce a product is regarded as a future good. For example, the totality of the factors of production required to produce an automobile that will be completed one year from now is regarded for purposes of valuation as a future automobile to be available in one year.

According to the time-preference theory, the fact that factors of production are future goods, which are less highly valued than present goods, is what explains the rate of return on capital. For example, the factors of production required for producing 10 apples to be available a year from today are valued as the equivalent of 10

future apples. But 10 future apples are of less value than 10 present apples. They may be of a value equivalent only to 9 present apples. Thus, the factors of production required for producing 10 future apples begin with a value equal to that of only 9 present apples. But now time passes. At the end of a year, the factors of production required for producing 10 future apples have succeeded in producing those apples. They have “matured” or “ripened” into 10 *present* apples. Thus, the totality of the factors of production required for producing 10 apples, which began with a value of only 9 present apples, has been transformed into 10 present apples, with a value of 10 present apples. In other words, profit exists because factors of production are future goods, which are purchased at a “discounted value” in comparison to present goods of the same kind and number, and then mature or ripen into present goods, which shake off that discount and sell at the full value appropriate to present goods. (This example, of course, is supposed to apply to *all* goods, inorganic as well as organic. Thus the factors of production required to produce an automobile or house are also held to begin as future goods and then to mature or ripen into the automobile or house.)

The nature of the process is clearly stated by Rothbard, who essentially does nothing more than adapt the illustration Böhm-Bawerk used against the exploitation theory and which I described in the course of my own critique of the exploitation theory.¹¹⁶ Thus, Rothbard writes:

Suppose, for example, that a capitalist-entrepreneur hires labor services, and suppose that it can be determined that this amount of labor service will result in a net revenue of 20 gold ounces to the product owner. We shall see below that the service will tend to be paid the net value of its product; but it will earn its product *discounted* by the time interval until sale. For if the labor service will reap 20 ounces five years from now, it is obvious that the owner of the labor cannot expect to receive from the capitalist the full 20 ounces *now*, in advance. He will receive his net earnings discounted by the going *agio*, the rate of interest. And the interest income will be earned by the capitalist who has assumed the task of advancing the present money. The capitalist then waits for five years until the product matures before recouping his money.

The pure capitalist, therefore, in performing a capital-advancing function in the productive system, plays a sort of intermediary role. He sells money (a present good) to factor owners in exchange for the services of their factors (prospective future goods). He holds these goods and continues to hire work on them until they have been transformed into consumers' goods (present goods), which are then sold to the public for money (a present good). The premium that he earns from the sale of present goods, compared to what he paid for future goods, is the *rate of interest* earned on the exchange.¹¹⁷

It should be obvious from this quotation that the

time-preference theory in its traditional form shares with Böhm-Bawerk's critique of the exploitation theory the enormous error of regarding the wage earners as the real producers of the products, rather than, as is in fact the case, the businessmen and capitalists. The businessmen and capitalists do not buy future goods from wage earners and suppliers. *They* are the producers of the future goods and have the first and only claim to them; their obligation to the wage earners is to pay the latter for *helping* them in the production of *their*—the businessmen's and capitalists'—products.¹¹⁸ But even if this error is put aside, further very serious difficulties remain for the time-preference theory in its traditional form.

First of all, the basic formula of the time-preference theory does not demonstrate what it is supposed to demonstrate. By that, I mean that the establishment of a relationship between the value of the factors of production expressed in terms of present goods, and the quantity of present goods that in the future will result from those factors of production, does not in fact convey any information whatever about the height of the rate of return. For example, the fact that 9 present apples are as valuable—in different circumstances—as the factors of production required for producing 10, 20, or 5 future apples, which, when the future comes to pass, will become 10, 20, or 5 present apples, actually says nothing whatever about the rate of return that is earned in producing those future apples. Starting with 9 present apples and ending with 10, 20, or 5 present apples a year later simply does not tell us the rate of return that is actually earned in production.

As evidence of this fact, let us assume that the price of an apple today is \$1 and that, in three different, alternative cases, the price of the factors of production required for producing 10, 20, or 5 apples to be available in a year is \$9. According to the time-preference theory, the rate of return implied in these three cases is 11 percent, 122 percent, and -44 percent, respectively. This is because next year, there will be 10, 20, or 5 present apples that result from factors of production bearing a value of 9 present apples of today. Thus, according to the time-preference theory, there is a gain (or loss) equal to 1, 11, and (4) units of present apples respectively, which, when divided by the initial 9 present apples, results in the three percentages of gain or loss just named.

It should be obvious that such inferences as to the rate of return rest on the unstated assumption that *the price of an apple in the future will be the same as it is in the present*. Only then would 10, 20, or 5 apples represent 10, 20, or 5 dollars of sales revenues and thus 1, 11, or 4 dollars of profit or loss and the corresponding rates of profit or loss implied. But in fact, there is absolutely no reason for assuming that the price of apples will stay the same over time. It will certainly not do so in the condi-

tions of an invariable money accompanied by changes on the side of production and supply. In such conditions, where the assumption that the price of present goods is constant must be abandoned, there is no way of inferring what the sales revenue, profit, and rate of return will be merely on the basis of the relationship between the value of factors of production expressed in terms of present goods and the quantities of present goods that will result from the factors of production in the future.

This point can be confirmed by means of our well-tried analysis featuring the output resulting from the use of *IK* of capital goods in conjunction with *IL* of labor. Recalling Figure 16-2, we have seen that in every year the monetary value of the factors of production required to produce the *IC* of consumers' goods of the following year is 400. We have also seen that the monetary value of the *IC* of consumers' goods sold both in the current year and in the following year is always 500. Thus, it follows that the value of the 400 worth of factors of production required to produce next year's consumers' goods, when expressed in terms of consumers' goods, is always .8*C*. That is to say, if 500 is the monetary value of *IC* of consumers' goods, 400 is the monetary value of .8*C* of consumers' goods. Consumers' goods, of course, are present goods. Thus, it is now established that in the analysis of Figure 16-2, .8*C* is the value of the factors of production of any given year, expressed in terms of present goods, that are required to produce the consumers' goods—the present goods—of the following year.

So long as everything remains stable, and thus the monetary value of *IC* of consumers' goods remains stable, the formula of the time-preference theory appears to be consistent with the monetary rate of profit, at least when it is stated as the gain in value relative to cost of production. Thus, in monetary terms, factors of production worth 400 monetary units produce consumers' goods worth 500 monetary units, and, at the same time, when expressed in terms of present goods, factors of production worth .8*C* produce *IC* of consumers' goods. As a result, whether expressed in money or in present goods, the ratio of the value of the product to the value of the factors of production used up to produce it is 5:4.

If, however, in the conditions of Figure 16-2, while everything else remained the same, the production of the economic system were to double between some particular year and the next (to choose a convenient multiple to work with), the formula of the time-preference theory would imply a very different rate of profit than the actual one. It would imply a rate of profit of 150 percent. This is because in this case, factors of production equivalent in exchange value to .8*C* of consumers' goods would produce a quantity of consumers' goods equal to 2*C*. According to the formula of the time-preference theory,

the gross rate of gain in value in terms of present goods in such a case would then equal $2C/.8C$, which is 2.5. When the initial capital is subtracted, this leaves a rate of net gain—a rate of profit—of 1.5, that is, 150 percent. Nevertheless, the monetary rate of profit expressed as a percentage of cost would not be 150 percent. It would still be just 25 percent. This is because in the conditions of an invariable money, the monetary value of the $2C$ of consumers' goods would be no greater than the monetary value of the $1C$ of consumers' goods was before. In monetary terms, it would still be a matter of 400 monetary units worth of factors of production producing a product worth 500 monetary units. The number of physical present units produced is simply irrelevant to the monetary rate of profit. The effect of their increase is merely to reduce prices, not to add to the rate of profit.

This example has provided a decisive test of the formula of the time-preference theory and has shown that the formula does not hold up. In fact, the example shows that the time-preference theory commits exactly the same kind of error as the productivity theory. Namely, both theories confuse ratios in terms of physical goods, with ratios of monetary value. The time-preference theory confuses the ratio of the present goods produced to the present-goods value of the factors of production used up to produce them, with the ratio of the monetary value of the present goods produced to the monetary value of the factors of production used up to produce them. The productivity theory confuses the ratio of the physical output produced to the physical capital goods used up to produce it, with the ratio of the monetary value of the output to the monetary value of the capital goods used up to produce it. Both theories confuse the physical product with a monetary value and take for granted that increases in the physical product mean equivalent increases in sales revenues, which is simply not the case, as analysis in terms of an invariable money conclusively shows. In contrast to the productivity theory, the time-preference theory's formula at least makes an allowance for the value of the labor expended in production, and thus the rate of profit it implies deviates from the actual rate somewhat less than does the marginal net physical productivity of capital goods.

It is perhaps not necessary to point out that in exactly the same way, under the conditions of Figure 16-2 and its invariable money, if the production of the economic system were to halve between some particular year and the next, the rate of profit would again remain the same. This, of course, is once again in full contradiction of the time-preference theory's formula, which implies that the rate of profit in this case must be in the ratio of $.5C$, which is the quantity of present goods one ends up with, to $.8C$, which is the present-goods value of the factors of pro-

duction used up to produce them. The fact is that instead of being -37.5 percent, as the time-preference theory's formula implies, the rate of profit would continue to be 25 percent when stated as a percentage of costs. This is because the $.5C$ would sell for the same 500 monetary units as $1C$ sold for, and thus the ratio of sales revenues to costs would still be 500:400.

Thus, in sum, the rate of return in monetary terms has nothing whatever to do with the relationship between the value of factors of production expressed in terms of present goods and the supply of present goods that will later on result from those factors of production. The difference between these two magnitudes of goods is simply irrelevant. What is relevant is the *monetary value* of the factors of production and the *monetary value* of the future goods later on, when they become present goods, that is to say, the sales revenues. The relevant relationship is that between two monetary values—the money sales revenues and the money costs—not that between two values expressed in terms of present goods. No valid inference whatever can be drawn from the quantity of present goods one ends up with to the sales revenues one ends up with. It is for this reason, that no valid inference can be drawn either as to the amount or rate of profit on the basis of differences in quantities of present goods represented by factors of production and their products.

The Contradiction Between Böhm-Bawerk's "First Cause" and the Doctrine of the Purchasing-Power Premiums

The error in the formula of the time-preference theory places the theory's supporters in essentially the same embarrassing situation as the supporters of the productivity theory and its offshoot the doctrine of secular stagnation.¹¹⁹ Just as the supporters of the productivity theory, who regard technological progress as the cause of a higher demand for capital and thus, allegedly, of a higher rate of profit, are ultimately placed in the contradictory position of regarding technological progress as the cause both of an increase and a decrease in the rate of profit,¹²⁰ so the supporters of the time-preference theory are led into the contradiction of regarding increases in production as the cause both of an increase and a decrease in the rate of profit!

On the one hand, the supporters of the time-preference theory correctly perceive an increase in production as reducing the value of future goods relative to present goods, because future goods will thus be more abundant relative to present goods. Indeed, Böhm-Bawerk describes this phenomenon as "the first cause" of the higher valuation of present goods over future goods.¹²¹ The mistaken formula of the time-preference theory then

leads them to believe that the rate of profit is correspondingly increased. (The example of a doubling of production can serve once again. Thus, if the same factors of production with a present-goods value of $.8C$ can produce $2C$ instead of just $1C$, $.8C$ of present goods is held to become the equivalent of $2C$ of future goods instead of only $1C$ of future goods. The implied ratio of future goods to present goods thus rises from 125 percent to 250 percent, and the rate of profit, allegedly, from 25 percent to 150 percent.)

Yet, on the other hand, when the supporters of the time-preference theory come to consider the effects of *the fall in prices* that an increased availability of goods in the future will bring about, they argue that the rate of profit and interest is correspondingly *reduced*—that it comes to incorporate a “negative price premium” that reduces it by a number of percentage points that is more or less equal to the percentage fall in prices.¹²² In this way, the same cause—rising production—is held both to raise *and* lower the rate of profit.

The truth is, of course, that increases in production neither raise nor lower the rate of profit. The fall in the value of future goods relative to present goods that an increase in production brings about does not raise the rate of profit, because, other things being equal, a larger future output will be sold for the same sales revenues as the alternative smaller future output, and will thus necessarily be accompanied by a corresponding fall in the selling prices of those future goods. The fall in the selling prices of the future goods does not lower the rate of profit because, by the same token, it is the accompaniment of a correspondingly larger quantity of goods to sell. Thus, when there are $2C$ instead of $1C$ as the product of factors of production worth $.8C$, the additional $1C$ does not add anything to the rate of profit because the $2C$ sell for the same sum of money as did the $1C$. By the same token, the halving of prices when there are $2C$ of product instead of $1C$ does not take anything away from the rate of profit, precisely because there are twice as many units to sell at the halved price, and thus sales revenues remain the same. The rate of profit itself, it must never be forgotten, is determined by the relationship between *the amount of money* for which goods can be sold in the future and *the amount of money* expended to produce them—irrespective of the physical quantity of the goods produced, irrespective of whether that quantity is larger or smaller than the quantity produced and sold in the present, and irrespective of whether the unit price of that quantity is less or greater than the price of goods in the present.¹²³

The Discounting Approach

The time-preference theory implies that one can take the prospective value of consumers' goods as *a fixed*

starting point, and that the value of factors of production is then straightaway derived from the value of consumers' goods by a process of compound discount. The causal chain, in its eyes, runs from the value of consumers' goods, together with rate of discount, to the value of factors of production. This belief is stated by Irving Fisher—one of the leading advocates of the time-preference theory—in the clearest possible terms:

The theory of prices, so far as it can be separated into parts, includes: (1) explanation of the prices of final services on which the prices of anterior interactions depend; (2) explanation of the prices of intermediate interactions, as dependent, through the rate of interest, on [the prices of] the final services; (3) explanation of the prices of capital instruments as dependent, through the rate of interest, upon the prices of their final services. *The first study, which seeks merely to determine the laws regulating the price of final services, is independent of the rate of interest.*¹²⁴

The notion that the prices of consumers' goods are independent of the rate of profit and can, therefore, serve as a fixed base for discounting is completely mistaken. Long ago, Ricardo demonstrated that changes in the rate of profit profoundly affect the prices of consumers' goods.¹²⁵ The following example shows precisely how they can do so.

Thus, assume that a quantity of wheat ready for harvesting and a quantity of eight-year-old scotch both regularly sell for \$100. If the rate of profit is 10 percent per annum, then, on the assumption that six months must elapse between the planting of the seed and the harvesting of the wheat, the value of the wheat when newly planted will be approximately \$95. At the same time, the newly fermenting alcohol corresponding to the prospective quantity of eight-year-old scotch worth \$100, will be worth approximately \$47. (These figures are implied by the fact at a 10 percent annual rate of return, \$95 is the approximate sum that grows to \$100 in six months, while \$47 is the approximate sum that grows to \$100 in eight years.)

Now let us imagine that the rate of profit falls to 5 percent per year. According to the discounting approach, the consequence will simply be that the value of the freshly planted wheat will rise to approximately \$97.50 from \$95, while the value of the newly fermenting alcohol will rise to approximately \$68 from \$47, for at a 5 percent annual rate of return, these are the sums that grow to \$100 in six months and in eight years respectively.

Nevertheless, insofar as the wheat and the scotch can both be produced by the same labor, such a result is simply impossible. This is because it would imply a much greater rise in the wages of the workers producing the scotch than in the wages of the workers producing the wheat. To see this as clearly as possible, let us substitute for the value of the newly planted wheat and newly fermenting alcohol the value of the labor required

to produce them. If the wheat is produced by 95 units of labor at an initial wage of \$1 per unit, while the scotch is produced by 47 units of labor, also at an initial wage of \$1 per unit (the wage rates are equal because the labor is assumed to be of the same kind), then a fall in the rate of profit which had no effect but to raise the prices of the factors of production, would imply that the wages of the workers producing the wheat rose in the very modest ratio of \$97.50 to \$95, while the wages of the workers producing the scotch rose in the much higher ratio of \$68 to \$47. Yet such a development would be impossible. Any significant rise in the wages of the one occupation relative to the wages of the other occupation would cause a movement of labor out of the relatively lower-paying occupation and into the relatively higher-paying occupation.

The actual effect in this case would be a significant and approximately equal rise in the wage rates of both groups of workers. Thus the rise in wage rates of the workers producing the scotch would be substantially less than in the ratio of \$68 to \$47, while the rise in the wage rates of the workers producing the wheat would be substantially greater than in the ratio of \$97.50 to \$95. Both of these developments would be the result of a movement of workers from wheat production to scotch production.

Now the clear implication of this movement of workers from wheat to scotch is an increase in the supply of scotch and decrease in the supply of wheat, which means that in the face of the same respective demands for scotch and wheat as prevailed before, *the price of scotch falls and the price of wheat rises*. Thus, the effect of the fall in the rate of profit, accompanied by a corresponding rise in the demand for labor and in wage rates, is *a change in the relative prices of different consumers' goods*. Consumers' goods requiring a relatively long period of time to produce, such as scotch, tend to fall in price; while consumers' goods requiring a relatively short period of time to produce, such as wheat, tend to rise in price, as the result of a combination of a fall in the rate of profit and rise in the demand for labor and thus in wage rates.

Because changes in the rate of profit are thus accompanied by changes in the prices of consumers' goods, one is not justified in holding that the value of factors of production is determined by a process of discounting independently determined prices of consumers' goods. It is simply impermissible to imagine that there is the value of consumers' goods and a rate of discount, and that these two then determine the value of the factors of production. This is because the rate of profit or, better, the forces determining the rate of profit also determine the value of consumers' goods, and do so insofar as these latter re-

quire time in their production. It is not the case that the causal chain runs from value of consumers' goods, together with rate of discount, to value of factors of production. Rather, the value of consumers' goods and the value of the factors of production used to produce them are *both* determined by the forces that determine the rate of profit. That is, they are both determined by the respective supplies of and demands for products and for factors of production, including the specific supplies of and demands for consumers' goods and producers' labor.

The discounting approach is, in fact, a denial of the law of supply and demand! I say this, because it seeks to exempt the formation of the prices of factors of production from the operation of that law. In its eyes, only the prices of consumers' goods are determined by supply and demand; the prices of the factors of production are held to be determined directly by the application of a discount to the prices of consumers' goods. The truth is that the prices of factors of production are determined by supply and demand no less than the prices of consumers' goods, and that the rate of discount (*viz.*, profit) then emerges as the result of *differences* between the demand/supply situation in the market for products and the demand/supply situation in the market for factors of production.

As an approximation, one may say that the difference between the demand for products, inclusive of capital goods, and the demand for factors of production, inclusive of capital goods, is represented by net consumption; while the difference between the supply of products and the supply of factors of production is represented by net investment—insofar as it takes place apart from the increase in the quantity of money and volume of spending. (Net investment of this type exists to the extent that the supply of products sold is less than the supply that corresponds to the factors of production previously purchased. The difference is retained within business firms as an addition to their assets and thus constitutes net investment.) As for the increase in the quantity of money and volume of spending, its effect is to make the demand for products further exceed the demand for the factors of production made in the past to produce them.

The rate of discount—of profit—is the effect of these differences in demand and supply, which, of course, at the same time are also the cause of the differences between the prices of products and the sum of the prices of the factors of production required to produce them. To the extent that the demand for products is greater than the demand for the factors of production used to produce them, or the supply of products is less than the supply of factors of production used to produce them, the prices of products exceed the sum of the prices of the factors of production and there is profit. Indeed, only to this extent is there profit.

The Disappearance of the Higher Value of Present Goods at the Margin: Böhm-Bawerk's Abandonment of the Time-Preference Theory

Yet another major problem arises for the time-preference theory in its traditional form. This is the fact that whoever has savings of any kind thereby demonstrates that he values the last unit of wealth that he devotes to the future above an additional unit of wealth that he might devote to enjoyment in the present. In other words, to this extent, at the margin, he has a *preference for future goods over present goods*. Other things being equal, for the reasons explained in Chapter 2, he undoubtedly values a unit of wealth occupying the same marginal position more highly in the present than in the future, whether it is the fifth, the fiftieth, or the five-hundredth unit.¹²⁶ Nevertheless, the fact that he regularly values *some* future units above additional present units—e.g., the fourth or four-hundredth future unit above the fifth or five-hundredth present unit—makes it incorrect to say that in the market present goods must always be more valuable than future goods. Because of the significance of valuation at the margin, there is no more reason for expecting such a relationship than to expect that water must be valued more highly in the market than diamonds. This is because there are almost always some units of future goods that at the margin are more valuable than present goods.

This was recognized by Böhm-Bawerk, and as a result of it, he virtually abandoned the time-preference theory. In a footnote to his exposition of the theory of interest, he declares:

There are persons who are excessively well provided for in the present, or at least would be, if they wished to use up completely all the means available to them in the present, including the principal of their fortunes. In their case this relation of wants to means of satisfaction engenders a tendency in the opposite direction, that is to say, toward a higher valuation of future goods. . . . This explains one point in connection with persons who command in the present greater means than, in deference to sound economy, they may permit themselves to consume in the present. I refer to the fact that they would regularly arrive at approximate *equivalence* in their valuation of present and future goods if the first two main causes [of a higher valuation of present over future goods] alone were operative. In their case the decision in favor of present goods can be brought about only through the operation of the third main cause the discussion of which follows immediately at this point in the text.¹²⁷

This passage is tantamount to a total abandonment of the time-preference theory by Böhm-Bawerk. This is because the “equivalence” in value between present and future goods at the margin applies to virtually everyone, since almost everyone has some amount of savings. Böhm-Bawerk confirms his abandonment of the time-

preference theory by shifting the weight of his argument from his first two main causes of a higher valuation of present goods in comparison with future goods, to his third main cause of such higher valuation. As explained earlier in this section, the meaning attached by Böhm-Bawerk to the “first main cause” is the prospective more abundant provision of goods in the future compared with the present. What he means by the “second main cause” is an alleged systematic undervaluation of the importance of future wants and the means of satisfying them.¹²⁸ Böhm-Bawerk’s reference to “the third main cause” as the decisive factor in the higher valuation of present over future goods refers to something that has nothing to do with time preference—namely, to an alleged “technological superiority” of present over future goods, resting on the alleged fact that the possession of present goods permits the adoption of more-time-consuming, more-productive processes of production. At this juncture, Böhm-Bawerk passes from the time-preference theory to a version of the productivity theory, which we need not consider further, since we have already fully refuted that doctrine.

Time preference, of course, does profoundly influence the rate of profit and interest, despite the fact that at the margin, future goods are preferred to present goods almost as often as present goods are preferred to future goods. The connection, as we have seen, is by virtue of its determining the rate of net consumption.

3. The Classical Basis of the Net-Consumption Theory

The role of net consumption as a determinant of profits is implicit in classical economics not only in John Stuart Mill’s proposition that “demand for commodities is not demand for labour,” which we have already considered at length,¹²⁹ but also in Ricardo’s proposition that “profits rise as wages fall and fall as wages rise.” While Ricardo’s proposition is open to various interpretations, at least some of the time it can be interpreted as tantamount to the net-consumption theory operating under certain highly restrictive assumptions. For example, Ricardo declares: “If a manufacturer always sold his goods for the same money, for £1,000, for example, his profits would depend on the price of the labour necessary to manufacture those goods. His profits would be less when wages amounted to £800 than when he paid only £600. In proportion then as wages rose would profits fall.”¹³⁰

If Ricardo’s proposition is interpreted to mean that under conditions of a fixed aggregate monetary demand for consumers’ goods, the amount of profit depends on the amount of wages paid, which latter is to be taken as equivalent to aggregate costs of production, then his

proposition is both true and fully consistent with the net-consumption theory.¹³¹ In fact, it should be obvious that on this interpretation, the proposition implicitly presupposes the existence of net consumption, in order for the demand for consumers' goods to exceed the demand for labor in the first place.

Indeed, interpreted in this way, Ricardo's theory provides a perfectly accurate description of the determinants of aggregate profit and the average rate of profit in the example of the fishermen with the boats and nets presented in the critique of the productivity theory earlier in this chapter.¹³² If, as that example assumes, a million fishermen are each paid a wage of \$2.50 per day and produce a quantity of fish which always sells for a total of \$3 million, then aggregate profit is \$500,000, and is so irrespective of the physical quantity of fish produced and sold. What determines aggregate profit in such circumstances is wages, not the physical output of fish produced.¹³³

The implicit connection between Ricardo's proposition and the role of net consumption is further reinforced when these words of John Stuart Mill are recalled, words with which Ricardo would surely have agreed: "I conceive that a person who buys commodities and consumes them himself, does no good to the labouring classes; and that it is only by what he *abstains from consuming*, and expends in direct payments to labourers in exchange for labour, that he benefits the labouring classes, or adds any thing to the amount of their employment."¹³⁴ If profits move in the opposite direction of wages, and wages in turn move in the opposite direction of the consumption of businessmen and capitalists, who are the parties who pay the wages, then profits rise as net consumption rises and fall as net consumption falls.¹³⁵

Ricardo's theory of profit is, of course, highly deficient both in limiting itself to the case of an invariable money and in ignoring the demand for capital goods. A satisfactory theory of profit must be able to explain the determinants of profit under conditions in which aggregate monetary demand changes. Furthermore, when the demand for capital goods is taken into account, it is clear that even under an invariable money, profits and wages can rise or fall in conjunction with opposite changes in the demand for capital goods as well as opposite changes in each other, and thus that either could change and not be accompanied by a change in the other. For example, the demand for capital goods could rise at the expense of a fall in net consumption and profits, with no increase in the demand for labor; or the demand for labor could rise at the expense of the demand for capital goods, with no change in the amount of profit.

These deficiencies are at least partially responsible for

Ricardo's apostasies on the subjects of machinery and war, which he arrives at on the basis of the mistaken assumption that the interests of wage earners always lie with a higher demand for labor, even when it is at the expense of the demand for capital goods or rests on a foundation of taxation.¹³⁶ This is because the restricted confines of his theory deprive him of the ability properly to analyze these cases.

Still a further deficiency of Ricardo's theory is that it never states what it is that allows the demand for consumers' goods to exceed the demand for labor, and thus for profits to exist in the first place. The concept of net consumption is present in Ricardo's theory only by implication, not by explicit statement.

Even more serious are Ricardo's equivocations concerning the word "wages." The limited validity of his theory depends on wages being understood as total wage payments, viz., as the aggregate demand for labor, and the aggregate demand for labor in turn being understood as the aggregate demand for factors of production as such, and this in the context of a fixed aggregate demand for goods as such. Under those conditions, a rise in wages is tantamount to a fall in net consumption. Unfortunately, Ricardo uses the term wages as representing the aggregate demand for labor only some of the time. At other times, he uses it to mean the wage rates of individual workers. Thus he often argues that increases in wage rates reduce the rate of profit, when in fact their effect is to raise prices.¹³⁷ When combined with his error of believing that increases in the price of necessities cause an increase in wage rates, this confusion leads to the corollary error that reductions in the price of necessities raise the rate of profit by virtue of reducing wage rates, a notion that plays an essential role in the Marxian exploitation theory.¹³⁸ A thorough critique of Ricardo's confusion concerning a rise in wage rates as the cause of a reduction in the rate of profit appears in the appendix to this section.

Ricardo's confusion between wage rates and the total amount of wages in the economic system has also given rise to the doctrine of the so-called Ricardo effect. This is the mistaken belief that a rise in wage rates encourages the use of machinery.¹³⁹ A rise in the amount of wages, assuming it is based on a fall in net consumption, means a fall in the amount and rate of profit, hence, an encouragement to the use of machinery.¹⁴⁰ A mere rise in wage rates, however, has no such effect. A rise in wage rates discourages the use of machinery fully as often as it encourages it. Thus, while a rise in the wage rates of workers in employments where the use of machinery might be substituted, can encourage the use of additional machinery, a rise in the wage rates of workers *producing* machines, or anything necessary to the production of

machines, discourages the use of machinery.

Furthermore, in raising the cost of production and prices of products and thus in reducing the quantities of goods demanded, increases in wage rates indirectly serve to reduce the quantities demanded of all the factors of production required to produce such goods, including the quantities of machines demanded in producing such goods. Thus, increases in wage rates not only cause unemployment and less production, but also, as part of the same process, on net balance actually reduce the overall use of machinery, along with that of all other factors of production.

Finally, even in those isolated instances in which forced increases in wage rates do lead to the greater use of machinery, the effect is in no sense a gain, but merely a diminution of the loss that is imposed. It is a fallacy to assume that in all conditions the use of machinery represents a gain. Whether or not it does so depends on a comparison of the cost of producing a product with and without the use of the machinery in question. If the cost of producing the product is less without the machinery, then there is no gain in producing it with the machinery. There is still no gain, but at most only a diminution of loss, if now a labor union artificially increases the cost of producing the product without the use of machinery, so that by comparison it becomes cheaper to produce the product by means of the use of the machinery. All that is present here is a lesser increase in cost, thanks to the use of the machinery, rather than a greater increase in cost. There is still, however, an increase in cost and corresponding loss.

Appendix to Section 3: Critique of Ricardo's Doctrine of the Falling Rate of Profit

As we have seen, Ricardo believed that the rate of profit has a tendency continually to fall. His version of this doctrine is closely connected with his errors concerning the "iron law of wages." First, he mistakenly believes, in direct contradiction of the facts, that "With the progress of society . . . one of the principal commodities [food] . . . has a tendency to become dearer from the greater difficulty of producing it."¹⁴¹ Then he proceeds to the fallacy that somehow in response to this, wage rates must rise to prevent the wage earner from being deprived of subsistence. On the basis of this alleged rise in wage rates, he concludes that there is a tendency toward a continually falling rate of profit.¹⁴²

The truth is that with the progress of society, food and everything else becomes less expensive in terms of the labor required to produce it, not more expensive. Even if, as is the case in non-division-of-labor societies, progress is so slow that population growth and the law of diminishing returns offset it, there is still no tendency for

the real cost of food or other necessities steadily to rise. Under such conditions, each fall in real cost is merely followed by a rise that pushes the average standard of living back to the level of "minimum subsistence," and at the utmost, only temporarily below it. There is never any continuing rise in the real cost of food and other necessities with the progress of society. A continuing rise in the real cost of food or other necessities could occur only as part of a process of social and economic retrogression, not progress. It would end with the collapse of society, followed by the extinction of the human race.

Ricardo is also mistaken in believing that a rise in wages must ensue in response to a higher cost of necessities. He is further mistaken in believing that if a rise in wages did ensue in such circumstances, it would reduce the rate of profit.

In part Ricardo's confusions are the result of his failure to make proper application of his own principle of analyzing economic phenomena in the framework of an invariable money. Had he rigorously adhered to his assumption of an invariable money, and conceived of it in terms of a fixed aggregate expenditure to buy the output of the economy, he might have avoided the confusions to which he fell prey.

First of all, he might have recognized that a growing supply of labor does not result in a combination of falling wages and rising prices—that it is not true that the "labourers" would be "doubly affected." Even if it were the case that because of the operation of the law of diminishing returns, more-than-proportionately-larger quantities of labor had to be applied to the production of additional quantities of agricultural commodities and minerals when population increased, the effect would still be lower prices of such commodities, not higher prices, though the fall in their prices would be less than the fall in wages. The situation would be an increase in the supply both of labor and of goods, with the increase in the supply of goods being less than the increase in the supply of labor. Thus prices would fall, but by less than wage rates.

Had Ricardo realized that the prices of agricultural commodities and minerals would fall, despite the increase in the quantity of labor required to produce them, he might well have avoided leaping to the totally unwarranted conclusion that wages would rise. He might have recognized the simple fact that in such circumstances the buying power of the wage earners would decline, and that if it declined below the point of "subsistence," the only remedy would be the extreme one implied in his own theory of wages, namely, a reduction in population followed by a consequent rise in the productivity of labor employed on land. This last would result in the prices of agricultural commodities and minerals rising less than

wage rates when the supply of labor declined as the result of a higher death rate.¹⁴³

Indeed, in the conditions of an invariable money, the pressure for a fall in wage rates would be truly overwhelming in the face of an increase in the supply of labor. This is because while the aggregate demand for the products of business would be fixed, the operation of the law of diminishing returns and growing difficulty of producing food and minerals would cause the demand for labor actually to fall. This would be the result of the ensuing growth in land "rents" displacing part of the demand for labor.¹⁴⁴

Furthermore, Ricardo should have known that any arbitrary rise in wage rates that might have been secured by the wage earners would have had to result in corresponding unemployment. And precisely this is the reason why, in a free economy, it would not occur, or, if somehow it did occur, would be quickly reversed.

This is because, contrary to Ricardo's utterly mistaken implicit assumption that the demand for labor will rise in the face of higher wage rates, there is simply no source of funds for the payment of higher wage rates to the same number of workers. And thus higher wage rates must result in the employment of fewer workers and the production and sale of fewer goods. The fact that the higher wage rates would result in the production and sale of fewer goods would mean that prices would have to rise. Their not rising in the face of decreased production and a fixed aggregate expenditure to buy goods would imply the depletion of inventories, which would be the only means of maintaining the quantity of goods made available for sale. Such depletion could certainly not go on indefinitely. And when it ended, prices would have to rise.

Ricardo considers the objection that a rise in wage rates would mean a rise in product prices rather than a fall in the rate of profit, but he rejects this conclusion, largely on following grounds:

To say that commodities are raised in price is the same thing as to say that money is lowered in relative value; for it is by commodities that the relative value of gold is estimated. If, then, all commodities rose in price, gold could not come from abroad to purchase those dear commodities, but it would go from home to be employed with advantage in purchasing the comparatively cheaper foreign commodities. It appears, then, that the rise of wages will not raise the prices of commodities, whether the metal from which money is made be produced at home or in a foreign country. All commodities cannot rise at the same time without an addition to the quantity of money. This addition could not be obtained at home, as we have already shown; nor could it be imported from abroad. To purchase any additional quantity of gold from abroad, commodities at home must be cheap, not dear. The importation of gold, and a rise in the price of all home-made commodities with which gold is purchased or paid for, are effects absolutely incompatible.¹⁴⁵

Ricardo is right in arguing that under an international gold standard, the importation of additional gold from abroad is incompatible with a rise in the prices of domestically produced commodities, that, in fact, gold would be exported. However, he is incorrect in arguing that prices in general can rise only if the quantity of money is increased. They can rise even if the quantity of money and volume of spending are decreased—if production decreases by still more. Precisely this is what happens in the present case, in which wage rates rise.

This is because in this context the decrease in the quantity of money and volume of spending is itself the cause of an equivalent further decrease in production and supply. In the face of any given level of wages rates and prices, less money and spending mean equivalently smaller quantities of goods and labor demanded, which last means an equivalently smaller quantity of labor employed and thus an equivalently smaller supply of goods produced. For example, in the face of any given level of wage rates and prices, 10 percent less money and spending in a country mean a 10 percent reduction in the quantity of goods and labor demanded and thus a 10 percent reduction in employment and production. A second 10 percent reduction in money and spending means a second such reduction in employment and production, and so on. Yet, over and above the reductions in the quantity of labor employed and output produced as the result of less money and spending, there still remains the reduction in employment and production as the result of the rise in wage rates itself.

That is, once the quantity of money and volume of spending stabilize at any point, however much they may have been reduced, the fact that wage rates are higher in the face of the demand for labor that then exists means an inversely proportionate reduction in the quantity of labor demanded and thus in employment and output. Thus, with a reduction in output in inverse proportion to the rise in wage rates, prices must rise in direct proportion to the rise in wage rates, no matter what has happened to the quantity of money and volume of spending. The outcome is dictated by the law of supply and demand.¹⁴⁶

The gold outflow Ricardo described goes on only until the point is reached at which the supply of products produced has fallen sufficiently to equal the smaller quantity of products demanded at the higher prices needed to cover the higher wage rates. The outcome can be viewed as the limitation to price increases imposed by foreign competition ultimately being overcome by virtue of the country's production being restricted to those goods in which it has sufficient comparative advantage to obtain the necessary higher prices. If there are no such goods, the arbitrary imposition of the higher wage rates would ultimately serve simply to destroy the country in

question as a seat of production.

Ricardo advances another argument attempting to show that product prices cannot rise because of a rise in wage rates. This is the claim that to the same degree that a rise in wage rates might tend to raise the value of commodities, it also tends to raise the value of gold, with the result that product prices—the exchange ratios of commodities against gold—remain unchanged.¹⁴⁷

Here Ricardo violates his normal assumption that the monetary unit possesses invariable value, and thus that all changes in the value of commodities proceed from the side of commodities, not from the side of money. He implicitly assumes that the rise in wage rates reduces the supply of gold to the same extent that it reduces the supply of other commodities, and, therefore, prevents any rise in their prices. This assumption is false, however. While a rise in wage rates does imply a reduction in the production of gold, it by no means implies a reduction in the supply of gold. This is because at any given time, the current production of gold, or any commodity money, constitutes only a small fraction of its total supply, which is the accumulation of many years of its production. A reduction in its current production would almost certainly imply merely a slowing down in the increase of its supply. Thus, the effect of the rise in wage rates would still be a rise in prices—at least in comparison with what they otherwise would have been. This would be the case insofar as the production of ordinary commodities was reduced in the face of the same or still increasing quantity of money and volume of spending.¹⁴⁸

Furthermore, as I have shown, profits as such are not a source of funds for the payment of additional wages; profits are an accounting abstraction. As we have seen, the only possible actual source of funds for the payment of a larger amount of total wages in response to a rise in wage rates would be a diversion of funds from the purchase of capital goods or from the personal consumption expenditure of the businessmen and capitalists. The diversion of funds from the purchase of capital goods to the payment of wages—even if it occurred—would not serve to reduce the amount or rate of profit. It would merely serve to reduce the supply of capital goods and the productivity of labor and thus to raise unit costs and prices all the more.

There is simply no reason to expect a diversion of funds from the personal consumption expenditure of businessmen and capitalists to the payment of wages. A higher degree of saving and productive expenditure—that is, a higher economic degree of capitalism—would be required. But there is no basis for such a development taking place merely because of an approach of real wages to subsistence.

Even if, in dire circumstances, employers could be

prevailed upon to increase the wages of their employees out of a sense of charity, the increase in the money paid to them would not be wages, but a charitable contribution. Any employer who appears to pay wages that are higher than those which, in accordance with the conditions of the market, he must pay, does not pay wages, but grants charity. It makes no difference whether the recipient is his son-in-law who is worth only \$25,000 per year, but to whom he pays \$50,000 in order to please his daughter, or any other employee or employees.

In the virtually impossible case of everyone's nominal wage coming to contain a significant component of charity, the fact would remain that the component would not be a portion of their wages, but a portion of the employer's own income or wealth which he saw fit to give away.

If it were merely their income that employers disposed of in this way, then, of course, profit would not be reduced. It would still be earned, but consumed in a different manner. Ironically, if it were not their income, but part of their capital that they chose to give away in charity, then, precisely as the result of a fall in productive expenditure relative to fixed sales revenues, the aggregate amount of profit in the economic system would actually *rise*, and so too, correspondingly, would the average rate of profit. This is because such a development would imply lower aggregate costs in the face of given aggregate sales revenues. What would be present here would be a rise in the rate of net consumption.¹⁴⁹

Thus, the essential effect of an arbitrary rise in wage rates, if it did occur, and were prevented from being reversed because of a lack of freedom of competition, would be unemployment and less production. The effect of this, in turn, would ultimately have to be a rise in prices sufficient to cover the higher wage rates, not, as Ricardo argues, a decline in the rate of profit. These observations, of course, remove all remaining basis both for Ricardo's belief in the tendency of the rate of profit to fall with an increase in population and for his related belief that the tendency toward a falling rate of profit is interrupted by improvements in the production of wage earners' necessities, which allegedly reduce wage rates and thus allegedly raise the rate of profit. As I have shown, the average rate of profit in the economic system is not determined by wage rates, and wage rates, of course, are not determined by the price of wage earners' necessities. Ricardo's argument for a falling rate of profit is simply incorrect in every essential respect.

4. Other Proponents of the Net-Consumption/Net-Investment Theory

I arrived at the essentials of the net-consumption/net-

investment theory in 1959, on the basis of the writings of the British classical economists and of Ludwig von Mises, and of a longstanding dispute with Murray Rothbard about whether or not the rate of profit had to fall as the accompaniment of capital accumulation.¹⁵⁰ At the time, and for a number of years thereafter, I believed the theory to be entirely my own, original discovery. In the course of writing my doctoral dissertation, however, in which I presented the substance of the theory and attempted to develop its leading implications, I learned that in the mid-1950s Joan Robinson had propounded, as I put it then, “a theory of profit which in form is almost indistinguishable from my own, though in substance it is much closer to Schumpeter’s theory.”¹⁵¹

Further investigation revealed that Mrs. Robinson, in turn, had been preceded by some twenty years by the Polish Marxist Michael Kalecki, from whose writings she had learned the doctrine. Kalecki’s exposition originally appeared in journal articles in 1935 and was later presented in his book *Theory of Economic Dynamics*, first published in 1952.¹⁵²

Apart from the fact that both of these authors are clearly in possession of the formula that aggregate profit equals the sum of net consumption plus net investment (though they do not use the expression “net consumption”), there is surprisingly little further similarity between the doctrine presented by them and the doctrine presented by me. This becomes clear even in the manner of arriving at the doctrine. I quote the substance of Kalecki’s derivation of the doctrine in full:

We may consider first the determinants of profits in a closed economy in which both government expenditure and taxation are negligible. Gross national product will thus be equal to the sum of gross investment (in fixed capital and inventories) and consumption. The value of gross national product will be divided between workers and capitalists, virtually nothing being paid in taxes. The income of workers consists of wages and salaries. The income of capitalists or gross profits includes depreciation and undistributed profits, dividends and withdrawals from unincorporated business, rent and interest. We thus have the following balance sheet of the gross national product, in which we distinguish between capitalists’ consumption and workers’ consumption:

Gross Profits	Gross Investment
Wages and Salaries	Capitalists’ Consumption
	Workers’ Consumption
Gross national product	Gross national product

If we make the additional assumption that workers do not save, then workers’ consumption is equal to their income. It follows directly then:

$$\text{Gross profits} = \text{Gross investment} + \text{capitalists' consumption.}$$

What is the significance of this equation? Does it mean that profits in a given period determine capitalists’ consumption and investment, or the reverse of this? The answer to this question depends on which of these items is directly subject to the decisions of capitalists. Now, it is clear that capitalists may decide to consume and to invest more in a given period than in the preceding one, but they cannot decide to earn more. It is, therefore, their investment and consumption decisions which determine profits, and not vice versa.¹⁵³

Not only is Kalecki’s theory very different than my own in terms of its derivation, but little or no similarity can be found in the major conclusions he draws from the theory. For example, Kalecki declares that “Another long-run influence considered, rentiers’ savings [i.e., the savings of businessmen and capitalists] was found to be *an obstacle rather than a stimulus to development.*”¹⁵⁴ Kalecki also seems to embrace the view that a high rate of profit is necessary for investment and that technological progress is necessary as a stimulus to investment. He writes:

Inventions which occur in the course of a given period make certain new investment projects more attractive. The influence of this factor is analogous to that of an increase in aggregate profits which in the course of a given period makes investment projects generally more attractive than they were at the beginning of this period. Each new invention like each increase in profits gives rise to certain additional investment decisions. A steady stream of inventions in its effect upon investment is comparable to a steady rate of increase in profits.¹⁵⁵

In Mrs. Robinson’s theory, the role of net consumption, which she calls “rentier expenditure” is entirely secondary. Thus, she declares:

So far we have abstracted from consumption out of profits and the existence of rentier income. This exclusion was made purely for the sake of exposition. Having established *the main lines of the analysis without rentiers*, [viz., without net consumption], we must now introduce them into the model. The political and social importance of consumption out of incomes derived from property is very far reaching, but so far as the analysis of accumulation is concerned we shall find that it complicates the argument *without requiring any substantial change.*¹⁵⁶

In all, Mrs. Robinson devotes about twenty pages of her 435-page book to the discussion of net consumption, including all of its ramifications.¹⁵⁷ In large measure the concept comes up only in connection with a discussion of the wage bill paid in the “investment sector” as making possible a surplus of sales receipts in the consumers’ goods industries over wages paid by the consumers’ goods industries alone.¹⁵⁸ Of these twenty pages, only a few paragraphs constitute either a discussion of the concept itself or an attempt to prove that it is a determinant

of profits. No connection whatever is seen to exist between net consumption and either Mill's proposition that demand for commodities is not demand for labor (which Mrs. Robinson frequently contradicts), or Ricardo's doctrine that "profits fall as wages rise." (Mill does not even appear in the index, and Ricardo is mentioned only in connection with the erroneous doctrine of the so-called Ricardo effect, to which Mrs. Robinson subscribes.¹⁵⁹) Kalecki too seems totally unaware of any connection between the concept of net consumption and the writings of the classical economists.

In Mrs. Robinson's eyes, the primary determinant of profits is what she calls "net investment." It is not the case, however, that this means we both have the same theory but each emphasize the determinant of profits which the other treats as subordinate. For what Mrs. Robinson and I mean by net investment are two entirely different things. I mean by the term the difference between the *monetary value* of the assets purchased by business enterprises and the *monetary value* of the assets

used up by business enterprises—i.e., the difference between productive expenditures and aggregate business costs. She means by the term the *physical* growth in the amount of goods between two points in time.¹⁶⁰ Thus her theory is in reality a quasi-productivity theory, along the lines of Schumpeter's theory.¹⁶¹

The fact that Mrs. Robinson, Kalecki, and I share the same essential formula for the determination of aggregate profit is nonetheless true, however surprising it may be, in view of all the enormous substantive differences that exist between us not only with respect to the development and application of the net-consumption/net-investment theory, but with respect to virtually every other aspect of economic theory. They are advocates of socialism, while I, of course, am an advocate of laissez-faire capitalism. Because of this, I could never conceive of cooperating with them in any manner, and thus I never attempted to contact Mrs. Robinson, who continued to be prominent in the economics profession for many years after I became aware of her theory of profit.

Notes

1. As I showed, saving is further necessary in order to make possible the purchase of all expensive consumers' goods. On these points, see above, pp. 694–696.

2. See above, pp. 696–697.

3. Concerning the Keynesian claim that the rate of profit is "too low," see below, pp. 867–878.

4. Actually, it will be somewhat larger. This is because the numerator will include profits that represent remuneration necessary to compete with the wages and salaries that the businessmen involved could earn by working elsewhere, as employees. As I have pointed out this is of particular significance in the case of small businessmen and introduces an element of permanent inequality in the rate of return on capital in favor of small business. On this point, see above, p. 186.

5. Cf. above, pp. 186–187. See also above, pp. 520–522.

6. Unfortunately, more often than not, the latter procedure is the practice today. See, for example, the discussion of the theory of capital in Paul Samuelson and William Nordhaus, *Economics*, 13th ed. (New York: McGraw Hill Book Company, 1989), pp. 720–725.

7. See above, p. 573.

8. See above, p. 176. See also above, p. 558.

9. See above, pp. 186–187.

10. See above, pp. 569–570 and 651–652.

11. For a discussion of the nature and necessity of time preference, see above, pp. 55–56.

12. See above, pp. 702–705.

13. See above, pp. 700–702.

14. There is an exception to the principle that the demand for capital goods is simultaneously business sales revenues. This is the case of the purchase of second-hand capital goods from sellers who are not dealers in the goods. For example, a restaurant's purchase of a used delivery truck from a bakery would

not constitute sales revenue to the bakery. The bakery's sales revenue is derived only from the sale of the goods it is in business to produce, namely, baked goods, not its old equipment, whose sale is merely incidental to its regular operations. The same would be true of the purchase of a land site from the bakery or almost any other business: namely, the proceeds would not constitute sales revenue to the seller. Similarly, some portion of what is a demand for second-hand capital goods from the perspective of the buyers might constitute receipts to consumers, which receipts are certainly not business sales revenues—for example, the purchase by a business of a used automobile or land site from a consumer. However, little error results from ignoring all such cases. And, for the sake of ease of analysis, that will be our practice. The reason that little error is entailed in this simplifying procedure is that insofar as the purchase of such capital goods results in costs that the buyers must deduct from their sales revenues, the sellers of the capital goods are generally placed in a position in which the costs they must deduct from their sales revenues are reduced. For example, when the bakery sells its old delivery truck, it need no longer depreciate the truck. In addition, to the extent that businesses acquire capital goods by buying used goods from consumers, there are likely to be approximately offsetting sales of used goods by businesses to consumers, with the result that the effect on costs to be deducted from sales revenues should be insignificant. Insofar as such items are not mutually offsetting, it will be found that any effect that might exist with respect to aggregate profits is accompanied by an offsetting effect in the form of capital gains or capital losses.

15. This assumption is actually compatible with the existence of extensive saving on the part of individual wage earners, insofar as their savings are used to finance consumption expenditures of other wage earners or have a counterpart in consump-

tion expenditures by wage earners that are financed by funds obtained from business firms in the form of extensions of credit. For elaboration of this point, see below, p. 735. Nevertheless, even though it is probably descriptively correct, the net-consumption theory does not depend on this assumption. Concerning this fact, see below, pp. 750–754.

16. See above, pp. 702–705.

17. See below, pp. 754–756.

18. For discussion and defense of these definitions, see above, p. 445.

19. See above, p. 710.

20. Strictly speaking, I should say, no counterpart in the kind of productive expenditure and costs that we are interested in, inasmuch as a portion of net consumption, as we know, is made out of interest payments from business. However, as I have explained, we exclude cost on account of interest and the productive expenditure that generates it, because we are interested in profits prededuction of such interest.

21. This assumption has been present at least implicitly since Figure 14–4.

22. The cost value of plant and equipment is present in the cost value of the *IK* of capital goods on hand, together with that of all other capital goods, such as the materials purchased by business. Because all plant and equipment is assumed to be used up in a single year, the distinction between gross plant and equipment and net plant and equipment disappears.

23. For the meaning of capital, see above, p. 449.

24. See above, pp. 700–702.

25. It is possible, of course, in certain circumstances that new and additional money could be introduced into the economic system to finance dividend, draw, or interest payments.

26. The point also applies to education loans. On the subject of why education does not constitute “human capital” and why the expenditure even for vocational education should not be treated as productive expenditure, see above, pp. 455–456.

27. Table 16–4, like Figure 16–2, shows complete data for Years 1 and 2.

28. Later discussion will show why, in the long run, the amount and rate of net consumption must always be significantly positive, and thus that productive expenditure could not lastingly equal, let alone exceed, sales revenues. See below, pp. 750–762 *passim*. See also below, pp. 856–859.

29. Cf. above, pp. 475–480.

30. The increase in the quantity of money has a similar influence on the monetary value of the capital invested in particular industries and countries. Thus, in the absence of an increase in the quantity of money and volume of spending in the economic system, since, say, 1900, the monetary value of the capital invested in the automobile industry would be greater, though not nearly as much greater as it in fact is, while the monetary value of the capital invested in railroads would be substantially smaller, instead of greater. In the same way, the monetary value of the capital invested in agriculture would be much smaller now than it was in 1900 instead of being greater, while that of the capital invested in industry and commerce would be larger but not nearly as much larger as it now is. The sum of the monetary values of the capitals invested in the United States would be greater, though not nearly as much greater as it in fact is, while that of Western Europe would be substantially smaller

instead of much greater. Over the last thirty years or so, the sum of the monetary values of the capitals invested in the United States would have declined substantially instead of increased, while that of Japan and South Korea rose substantially, though much less substantially than they actually have risen.

31. See above, pp. 327–328.

32. The calculations of net consumption are based on data appearing in U.S. Department of Commerce, Office of Business Economics, *The National Income and Product Accounts of the United States, 1929–1965 Statistical Tables* (Washington, D. C.: U.S. Government Printing Office, n.d.), pp. 14, 150, 152. The amounts of net consumption were calculated by adding up the totals for proprietors’ income, corporate profits before tax, rental income of persons, and net interest, and then subtracting the respective magnitudes of negative net investment which, for their part, were found by subtracting capital consumption allowances from gross private domestic investment. In the process all imputations and inventory valuation adjustments were excluded. The subtraction of net investment from profits in order to arrive at net consumption is indicated by the fact that profits equal the sum of net consumption plus net investment, as we already know. See above, p. 723. Indeed, there we saw directly that net consumption is the difference between profits and net investment.

33. Later discussion will show that nothing depends on the individual having an entire year’s income available to him at the beginning of the year. Exactly the same results would follow if he had only a quarter’s income available to him at the beginning of a quarter, or a month’s income available to him at the beginning of a month, or even just a single day’s income available to him at the beginning of a day. See below, p. 743.

34. The elimination of negative net investment must take place far short of the point of the exhaustion of assets. As we shall see later in this chapter, the lower is the general rate of profit, the more powerful is the inducement to net investment and thus necessarily the elimination of any negative net investment. See below, pp. 779–784.

35. On the origin of money cf. Carl Menger, *Principles of Economics* (Glencoe, Ill.: The Free Press, 1950), pp. 257–271. See also, above, pp. 506–508.

36. On Smith and the status of consumption and profit in the “early and rude state of society,” see above, pp. 475–480.

37. Of course, in order for a high rate of profit actually to be heavily saved and in fact result in the accumulation of a fortune, the individuals in question must attach a greater value to the larger sum of wealth in the future than to the consumption which must be forgone in order to accumulate it. If this is not the case, then even the highest rates of profit do not result in the accumulation of capital.

38. Friedman’s doctrine is known as “the permanent income hypothesis.” See Milton Friedman, *A Theory of the Consumption Function* (Princeton, N. J.: Princeton University Press, 1957.)

39. Our previous examples concerning the consumption of businessmen and capitalists were constructed on the implicit assumption of a twenty-one year time horizon applied to the consumption of previously accumulated capital and current profit/interest income taken together.

40. Concerning the positive connection between the rate of

profit in real and in monetary terms and the rate of economic progress, see below, p. 775.

41. See above, pp. 55–56.

42. Cf. the discussion of the time preference theory in its traditional form, below, pp. 792–794.

43. See above, pp. 741–743.

44. The 5 percent figure follows from the fact that where i is the annual income on capital and equals $\frac{1}{21} \times (K + i)$, then

$21i = K + i$ and thus $20i = K$. This last means that $i = \frac{K}{20}$.

45. It is not necessary, of course, that the concept of time horizon be applied in an all-or-nothing way, in which even provision is made for all the years lying within it and none at all for the years lying beyond it. It might be, for example, that one wants to make even provision for each of the next 10 years and then 50 percent provision for each of the 20 years beyond that. That would be equivalent to having a time horizon in which one wished to make even provision for the next 20 years.

46. See above, p. 58. See also above, pp. 19–21.

47. See above, pp. 702–705. See especially, Table 15–2, on p. 705.

48. Unlike Table 16–3, Table 16–5 shows complete data for *Years 1* and 2, as did Figure 16–2 and Table 16–4.

49. It should be realized that from the point of view of the magnitude of sales revenues, it is indifferent whether the 100 of additional demand generated by productive expenditure represents 100 of additional demand for capital goods or 100 of additional demand for labor by business resulting in 100 of additional demand for consumers' goods by the wage earners of business, or any combination of such additional demands for the products of business totaling 100.

50. See above, pp. 702–705, especially Table 15–2, on p. 705, and the discussion accompanying it. It should be understood that we are temporarily ignoring taxation and thus the presence of taxes in costs.

51. Net investment and profits are 100 larger in Table 16–9 than in Table 16–8—i.e., 300 and 200 respectively versus 200 and 100 respectively—because the 100 of wage-earner saving is spent for capital goods rather than being hoarded or turned back to business in the form of loans or securities purchases to finance productive expenditure in the following period. In being spent in this way, it adds 100 both to productive expenditure and to sales revenues. In enlarging both productive expenditure and sales revenues by 100 in the face of the same aggregate costs of 600, it adds 100 to both net investment and profits.

52. See above, pp. 648–650.

53. The same principles, to be sure, apply to the use of income other than wages either to pay consumer interest or to purchase consumers' labor.

54. For elaboration of this point, see below, pp. 758–759.

55. It should be realized that the firm's annual depreciation charge never comes to exceed a million dollars, or whatever the assumed constant amount of annual expenditure for the assets in question may be. This is because once an asset reaches the end of its depreciable life, it no longer contributes to current depreciation. In the case of assets with a 20-year depreciable life, in every year from *Year 21* on the depreciation on new assets acquired in the current year merely takes the place of the

depreciation of assets now 21 years old and therefore already fully depreciated and no longer subject to additional depreciation.

56. Net investment in connection with the acquisition of land usually does not have a counterpart in aggregate profit, inasmuch as the funds expended in the purchase of land generally do not constitute a sales revenue, but merely receipts from the sale of existing capital or consumer assets. Such net investment does, however, have a counterpart in a *capital gain*, to the extent that a business seller's proceeds from the sale of land exceed his own previous acquisition cost of the land.

57. This usage of the concept of marginal productivity must be distinguished from the common one, in which the concept primarily denotes a net *physical* product attributable to the employment of additional capital goods. For a detailed explanation and discussion of the common usage, see below, pp. 787–788.

58. See below, pp. 787–792, for a detailed critique of the so-called productivity theory of profit/interest.

59. Net investment will not become negative if what places the rate of profit above the marginal productivity of capital is itself the existence of significant net investment and thus the existence of a significant net investment component in the rate of profit. In such a case, the effect will merely be a reduction in the amount of net investment and the size of the net investment component in the rate of profit.

60. The equalization of the rate of profit and the marginal productivity of capital in the sense in which I have been using the concept should not be taken to imply any claim on my part that the rate of profit tends to equalize with the marginal productivity of capital in the usual sense of a marginal net physical product attributable to capital goods. To the contrary, as I will show in my critique of the productivity theory, my analysis of capital accumulation implies that the general marginal net productivity of capital in *this* sense is permanently and substantially higher than the rate of profit. See below, pp. 787–792. The mistaken belief that the rate of profit and the marginal net physical productivity of capital goods tend to equalize leads to the error of taking the rate of profit as the measure of the physical contribution of capital goods to production, which in turn leads to the error of grossly understating the importance of capital goods to production and its increase. On this subject, see below, pp. 776–778. The mistaken belief that the rate of profit and the marginal net physical productivity of capital goods tend to equalize leads to the error of taking the rate of profit as the measure of the physical contribution of capital goods to production, which in turn leads to the error of grossly understating the importance of capital goods to production and its increase. On this subject, see below, pp. 776–778.

61. Concerning the nonsacrificial character of capital accumulation under capitalism, see above, pp. 639–641.

62. See above, pp. 723–725.

63. Concerning the various ways in which a lower rate of profit operates to encourage greater capital intensity, see below, pp. 778–784.

64. The present discussion confirms the view of von Mises that time preference—here operating through the rate of net consumption—is what accounts for the fact that more productive but more time-consuming processes of production are not automatically adopted. See Ludwig von Mises, *Human Action*,

3d ed. rev. (Chicago: Henry Regnery Co., 1966), pp. 482–483, 526.

65. The contribution of wage earners to net consumption exists insofar as they themselves have accumulated sufficient savings, whether in the form of capital or consumer loans, to place them in a position to consume in excess of their wages.

66. In conformity with the actual circumstances of business life, this last can be assumed to constitute a relatively small portion.

67. On the nature of NNP, see above, pp. 675–676 and 700–702. Capital-output ratios as typically computed include in capital the value of owner-occupied housing and the land on which it stands. Capital computed in this way can be taken as an approximation of total accumulated invested savings in the economic system; a virtually exact equivalence would be achieved if the value of homeowners' equity were subtracted and the value of interest-bearing consumer loans other than home mortgages were added. (The value of home mortgages is already implicitly included.)

68. We have already encountered this expression of the capital-output ratio. See above, pp. 302 and 364, in particular in the refutation of the argument that free immigration must reduce the ratio of capital to labor.

69. Concerning the relationship between net national product and national income and the fact that both are necessarily close in amount to consumption, see above, pp. 700–702 and 712.

70. In addition, it should be recalled that net investment is not an actual expenditure, nor, therefore, a demand, as the term is used in this book. On this point, see above, p. 717, n. 60.

71. Though static in terms of monetary magnitudes, such a state of affairs is, of course, perfectly compatible with a rising physical volume of production both of consumers' goods and of capital goods, though a 2:1 capital-net-output ratio would probably be far too low to bring about economic progress in actual practice.

72. See above, pp. 631–632.

73. See above, pp. 228–230, and below, pp. 774–775. For discussion of the analogous distinctions between monetary demand and real demand, and between money wages and real wages, see above, pp. 559–561 and 618–622.

74. See above, pp. 63–66.

75. See above, pp. 531–532.

76. It should be noted that in *Year 4* of Figure 16–3, wage payments and net consumption are rounded and thus do not quite add to the demand for consumers' goods.

77. Because of limited space, all data in the table is rounded to the nearest integer, except for the rate of profit and the change in the rate of profit, which are carried to two decimal places.

78. For an important qualification concerning this last proposition, see below, p. 773.

79. See above, pp. 758–759.

80. Again, see below, for an important qualification concerning the effect of the rate of increase in the quantity of money on the rate of net consumption.

81. See below, pp. 930–937 passim.

82. See below, pp. 951–963, for the full case for a 100-percent-reserve precious metals system.

83. Concerning this aspect of Say's Law, see above, pp. 559–561.

84. These observations confirm previous discussion in connec-

tion with the critique of the demands of labor unions for the paying over of profits as wages. See above, pp. 654–655.

85. See above, pp. 762–763.

86. See above, pp. 754–756.

87. See above, pp. 768–771.

88. For a discussion of the temporal relationship of productive expenditure to sales revenues, see again pp. 768–771, above. See also, below, pp. 820–824.

89. See, for instance, Moses Abramovitz, *Resource and Output Trends in the United States Since 1870* (New York: National Bureau of Economic Research Occasional Paper, no. 52, 1956), pp. 6, 8; and Robert M. Solow, "Technical Change and the Aggregate Production Function," *The Review of Economics and Statistics*, 39, August 1957. See also, above, the quotation from Samuelson and Nordhaus on pp. 630–631, where it is claimed that the rise in the productivity of labor is due mainly to technological progress as opposed to capital accumulation.

90. See, for example, the writings of Abramovitz and Solow cited above.

91. Curiously, in a backhanded way, Abramovitz ends up conceding the actual importance of capital accumulation. After first claiming that "the input of resources per head of the population appears to have increased relatively little, while the productivity of resources increased a great deal" in bringing about "the quadrupling—more or less—of net national product per capita," he ends by acknowledging that "capital per head of the population approximately tripled." This apparent blatant contradiction of first maintaining that an increase in capital per head has not significantly contributed to the increase in output per capita, and then declaring that a fourfold increase in output per capita has been accompanied by a threefold increase in capital per capita, is left altogether unexplained. See Abramovitz, pp. 8, 10.

92. See above, pp. 712–714.

93. See above, pp. 648–650.

94. The principle that a fall in revenue relative to capital creates a need for more capital accords with my previous finding concerning the significance of high capital requirements. That finding was that far from representing any kind of infringement of the freedom of competition, high capital requirements are evidence of the existence of high competitive standards. A large capital, I showed, is necessary in order to achieve the low costs needed to be profitable in the face of the low prices charged by others. See above, p. 376.

95. On this subject, see above, Chapter 6, n. 1.

96. For an account of the various specific ways in which this can occur, see above, pp. 754–756.

97. Within the borders of any individual country, of course, an increase in the quantity of commodity money is achieved as soon and insofar as the country's increased production increases its share of world production and thus of the money supply of the world economy.

98. The significance of negative net investment in counteracting the influence of net consumption in the generation of profits is indicated by the data for the years 1932 and 1933, cited above, on pp. 739–740.

99. See above, pp. 589–590. See also the preceding note.

100. Actually, a 5 percent annual increase in the money supply raises the rate of profit to slightly more than 10 percent, in that

1.05 times 1.05 is slightly more than 1.10. This kind of result is implicit insofar as there is any induced rise in the rate of net consumption.

101. The same, of course, would be true of a rise in the rate of profit attributable to a rise in the rate of net investment that occurred independently of the increase in the quantity of money.

102. Concerning the undermining of capital formation by means of the overconsumption that inflation causes, see below, pp. 930–937 *passim*.

103. See above, pp. 576–578.

128. See *ibid.*, pp. 268–273.

129. See above, pp. 683–685, 720–721, and 725–734.

130. Ricardo, *Principles of Political Economy and Taxation*, chap. 6 [p. 111].

131. It is relevant to note that Ricardo's chapter "On Profits," in which the above passage appears, contains an opening footnote reminding the reader that "I consider money to be invariable in value." This, of course, means the assumption of a fixed aggregate value of the consumers' goods.

132. Cf. above, pp. 787–790.

133. This interpretation of Ricardo's theory, I believe, is fully consistent with his discussion of value in sec. 7 of his chapter on that subject, and helps greatly to clarify that discussion. See above, pp. 495–496.

134. See above, pp. 683–684. Italics added.

135. Essentially the same point was made earlier, in my critique of the exploitation theory. See above, pp. 478–480.

136. See above, pp. 647–650.

137. See above, pp. 494–495.

138. See above, *ibid.* See also above, pp. 607–642.

139. Cf. von Mises, *Human Action*, pp. 773–776.

140. For the explanation of how a lower rate of profit encourages greater capital intensiveness, see above, pp. 779–784.

141. Ricardo, *Principles of Political Economy and Taxation*, chap. 5 [p. 93].

142. See above, pp. 494–495.

143. It must be kept in mind that the conditions being described are those of an essentially stagnant society, such as existed prior to the Industrial Revolution, certainly not those of laissez-faire capitalism.

144. Concerning the reduction in the demand for labor as the result of the rise in land rents, see above, p. 668.

145. Ricardo, *Principles of Political Economy and Taxation*, chap. 5 [p. 105].

146. The only thing that would prevent prices from rising in proportion to wage rates would be the extent to which a reduced volume of production might be accompanied by a higher productivity of labor. However, such a result is extremely unlikely in view of the greater efficiencies in a division-of-labor society that are the result precisely of the employment of a larger number of workers rather than a smaller number of workers.

147. Cf. Ricardo, *Principles of Political Economy and Taxation*, chap. 1, sec. 3 [p. 28].

148. The reduction in the production of gold would, however, imply a modest reduction in the rate of profit, inasmuch as it would mean a reduction in the rate of increase in spending of all kinds and thus in the rate of net investment. Such a reduction would be of a nonrepeatable nature inasmuch as wage rates could not continue to be arbitrarily driven up in the face of the mounting unemployment that would result. On this last point, see below, pp. 909–911.

149. For elaboration of the principles and mechanisms involved, see above, pp. 725–734.

150. As stated in the Preface, I maintained that it did not; he maintained that it did.

CHAPTER 17

APPLICATIONS OF THE INVARIABLE-MONEY/ NET-CONSUMPTION ANALYSIS

1. The Analytical Framework

In this chapter, I develop, or further elaborate on, a wide variety of major implications and applications of the net-consumption/net-investment theory which could not be presented in the course of expounding the basic theory itself. These concern the effects on the rate of profit (or, in some cases, lack of effect), of capital accumulation, falling prices caused by increased production, technological progress, taxation, government budget deficits, the so-called international balance of trade, and net saving. I also further develop the implications of the theory insofar as they pertain to the so-called average period of production, the relationship between capital intensiveness and technological progress, the doctrine of price premiums in the rate of interest, the process by which real wages are increased, and the theory of saving in general. In connection with the subject of saving, I develop the contrasting significance of net saving under an invariable money and under a money whose quantity increases, and thus show both the relationship between increases in the quantity of money and net saving and that the actual significance of saving lies at the gross level rather than the net level. I also develop the implications of my analysis for the critique of such prominent fallacies respecting saving as the doctrines of underconsumptionism and the alleged lack of profitable investment opportunities.

In order to develop all these implications, it is necessary to return to the assumption of an invariable money, despite the fact that under a commodity-money system the virtually inevitable effect of economic progress is to bring about an increase in the quantity of money and volume of spending. The assumption of an invariable money is necessary in order to understand the *separate connections* of phenomena to the rate of net consumption and to the rate of increase in the quantity of money—and, of course, to the rate of net investment apart from the increase in the quantity of money. Because it makes it possible to relate phenomena to the separate elements determining the rate of profit, the assumption of an invariable money is essential to the understanding of practically every aspect of the theory of profit and its applications.

For the sake of simplicity, it is also necessary to return to the further assumptions that all capital goods and labor in existence at the beginning of a year are entirely used up in producing the capital goods and consumers' goods that are available at the start of the following year and that all financial transactions take place on a single day, at the beginning of each year.

Thus, to carry our analysis further, we must turn now to Figure 17–1 “Profits in a Progressing Economy with an Invariable Money.” Figure 17–1 represents exactly the same kind of analysis of assets and spending and revenue as presented in Figure 16–2, but in combination

Figure 16-2
The Elements Determining the Average Rate of Profit

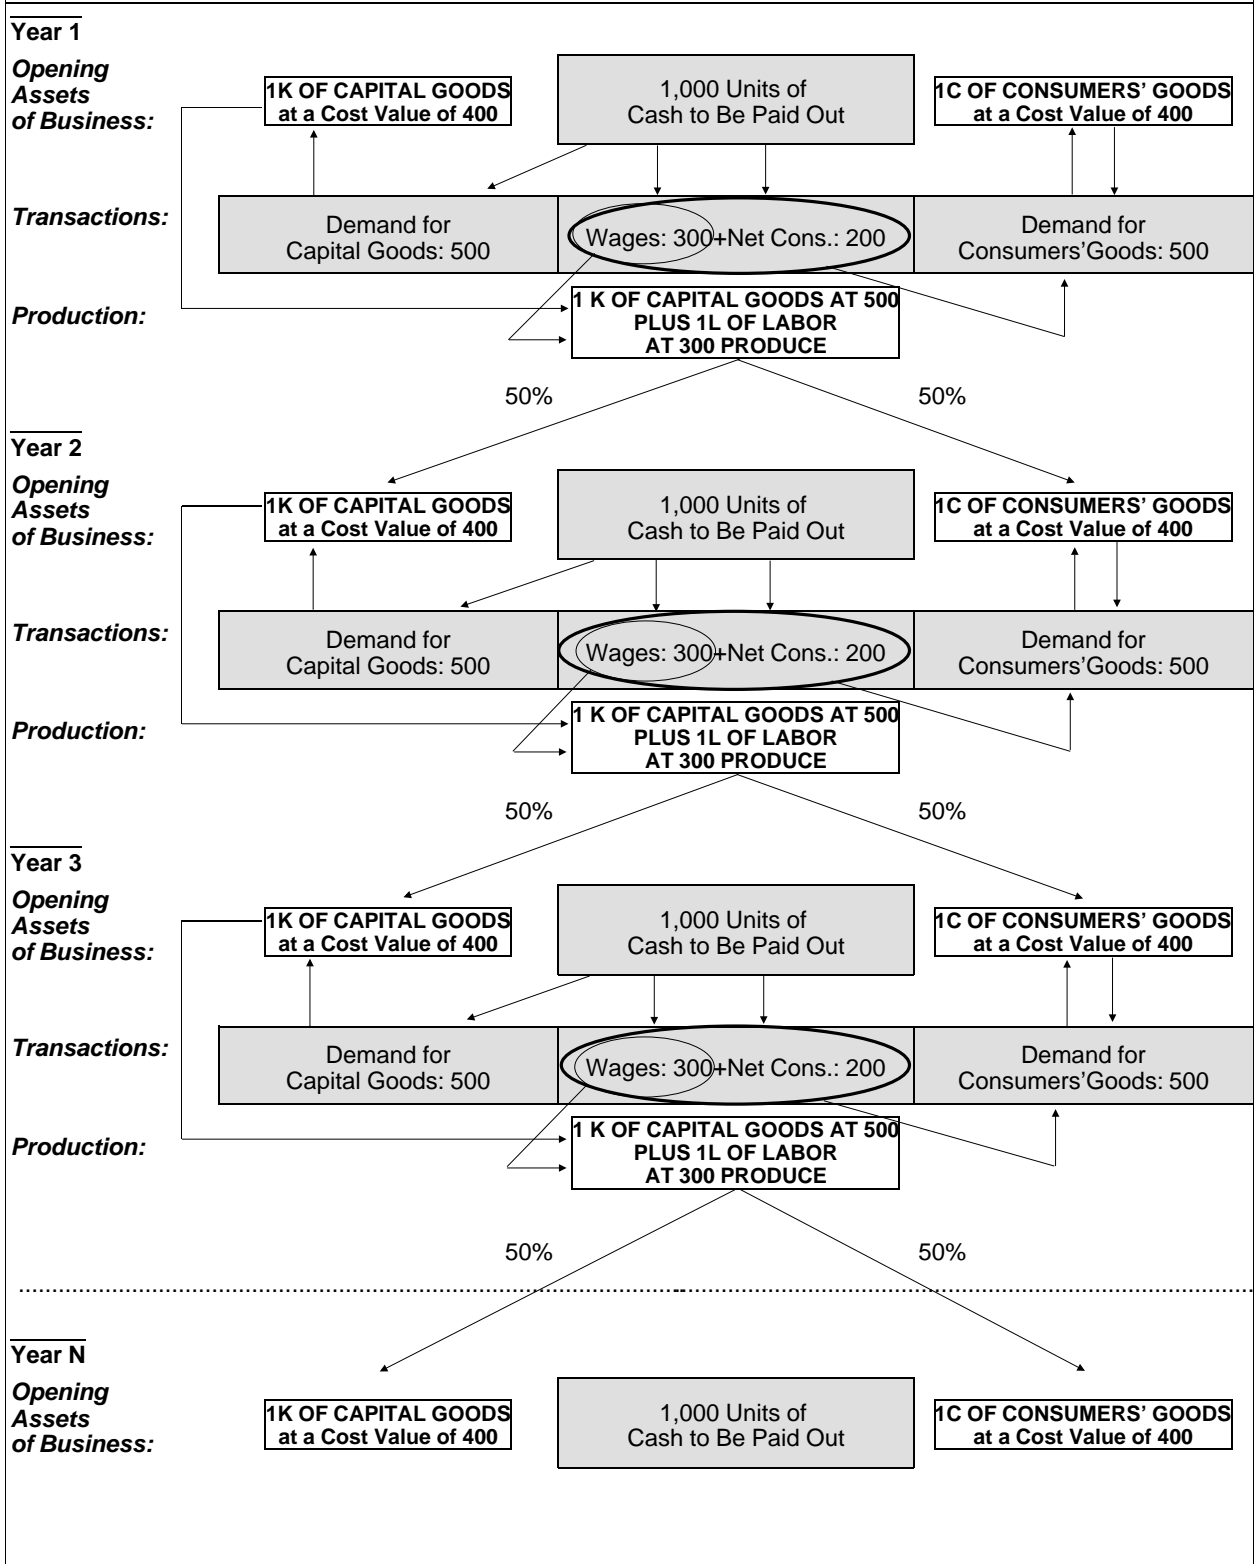

Figure 17-1

Profits in a Progressing Economy with an Invariable Money

with the capital accumulation and rising production depicted back in Figures 14–5 and 15–6. Figure 17–1 is to Figure 16–2, as Figure 14–5 is to Figure 14–4, and as Figure 15–6 is to Figure 15–5. For the reader's convenience, Figure 16–2 is reproduced preceding and facing Figure 17–1.

Strictly speaking, Figure 17–1 is somewhat more elaborate than Figure 16–2 in that, in addition to showing the course of capital accumulation from *Year 2* on, it also depicts the transition from a stationary economy to a progressing economy. *Year 1* of Figure 17–1 opens in exactly the same way as do all the years described in Figure 16–2. Even the financial transactions of *Year 1* of Figure 17–1 are identical with those of the years described in Figure 16–2. The transition to the conditions of a progressing economy begins to take place only in the production phase of *Year 1*. Here the 1K of capital goods purchased at the start of the year for 500 units of money, and the 1L of labor purchased for 300 units of money, come to be employed 60 percent in the production of capital goods and only 40 percent in the production of consumers' goods. In other words, the relative production of capital goods now rises to a level at which capital accumulation and economic progress will take place.

This change in the relative production of capital goods from the conditions of Figure 16–2 is, of course, the result of correctly anticipating the change in the relative demands for capital goods and consumers' goods which will occur in *Year 2* and remain in place thereafter. In *Year 2*, and every year thereafter, the demand for capital goods will stand at 600 units of money rather than the 500 of *Year 1* and all the years of Figure 16–2. By the same token, the demand for consumers' goods in *Year 2*, and every year thereafter, will stand at only 400 units of money rather than 500. Thus, exactly as in the earlier analysis of capital accumulation depicted in Figures 14–5 and 15–6, the $\frac{60}{40}$ relative production of capital goods takes place in response to the correct anticipation of the relative demands for capital goods and consumers' goods coming to stand in a $\frac{60}{40}$ ratio.

The $\frac{60}{40}$ relative production of capital goods is sufficient to achieve capital accumulation because, just as before, it is assumed that for each existing 1K of capital goods employed in conjunction with 1L of labor, it is possible to produce combinations of capital goods and consumers' goods within the limiting extremes of 2K, 0C and 0K, 2C.¹ Thus, as in Figures 14–5 and 15–6, starting with 1K of capital goods, a $\frac{60}{40}$ relative production results in 1.2K of capital goods and .8C of consumers' goods.

Figure 17–1 provides a direct means of understanding

the relationship between the rate of profit in the economic system and all manner of other major economic phenomena. In the space of a single page, it provides an analytical framework representing the essential elements of the productive process under the conditions of economic progress. In so doing, it makes it possible to intellectually grasp their operation and mutual interconnection virtually by a process of direct observation. To know and understand, for example, the relationship between the rate of profit and capital accumulation, or between the rate of profit and falling prices caused by increasing production, such as results from capital accumulation, all one need do is look at Figure 17–1, and then explain what one observes in terms of further information either presented in the figure itself or at least readily suggested by it and derivable from it. In effect, the figure constitutes a virtual laboratory in which one captures the essential pattern of economic progress in a monetary economy in an intellectually manageable size, and is then able to look at it from every possible angle and, as it were, poke and prod it and see exactly how it responds.

Thus, the figure shows that starting in *Year 2* capital accumulation takes place at a 20 percent compound-annual rate and that, as a result, starting at the beginning of *Year 3*, the total supply of goods available for sale in the economic system increases at a 20 percent compound-annual rate.² Since the demands for capital goods and consumers' goods are both assumed to be fixed at 600 and 400 units of money respectively in every year from *Year 2* on, the increases in supply that take place in every year starting from *Year 3* on imply correspondingly falling prices every year, that is, prices which fall in inverse proportion to the increase in supply, namely, in the ratio of 5:6.

Observe. Even though the figure stops with *Year 4*, for lack of space for additional years, it should be taken as projecting the continuation of the relationship between *Years 3* and *4* into the indefinite future. Thus, year after year, the figure shows both capital accumulation and the implication of falling prices resulting from the increase in production caused by capital accumulation. However, it also clearly implies a definite rate of profit in each of those years, on the basis of the various monetary transactions generating sales revenues, costs, and capital values. The figure thus provides an ideal analytical framework within which to ask and answer the questions: "Does the process of capital accumulation require or cause a falling rate of profit?" and, "Do falling prices caused by increasing production reduce the rate of profit?" The answer to these and other important questions can now be found by a process of simple inspection.³

2. Why Capital Accumulation and the Falling Prices Caused by Increased Production Do Not Imply a Falling Rate of Profit

And just what are the answers to the above two questions concerning whether or not capital accumulation and the falling prices caused by increased production imply a falling rate of profit? On the basis of Figure 17–1, the answers are clearly in the negative. This is because Figure 17–1 shows that in every year, from *Year 3* on, while capital goes on accumulating at a rate of 20 percent and prices fall at the inversely proportionate rate of $16\frac{2}{3}$ percent, the rate of profit remains *constant* at slightly more than 5 percent.

This rate of profit reflects the existence year after year of 1,000 monetary units of sales revenues in the economic system, 900 monetary units of productive expenditure (which is the sum of 600 of demand for capital goods plus 300 of wage payments or demand for labor), and 1,900 of total monetary value of accumulated capital. These data result in an amount of profit of 100—viz., 1,000 of sales revenues minus 900 of costs generated by the previous year's productive expenditure. When this amount of profit is divided by the 1,900 of capital, the resulting rate of profit is 5.26 percent.

The value of accumulated capital from *Year 3* on is the sum of opening inventories of capital goods with a cost value of 540 and consumers' goods with a cost value of 360, plus 1,000 units of cash to be paid out. The cost values of 540 and 360 for the opening inventories of capital goods and consumers' goods derive from the preceding year's productive expenditure of 900 applied 60 percent to the production of capital goods and 40 percent to the production of consumers' goods. These cost values, when the goods in question are sold for the 600 annual demand for capital goods and the 400 annual demand for consumers' goods, imply an annual amount of profit of 100 units of money ($100 = 600 - 540 + 400 - 360$). As I say, the division of this 100 of profit by the 1,900 of monetary value of accumulated capital then gives an average rate of profit of 5.26 percent.

As promised, Figure 17–1 also contains the *explanation* of why capital accumulation and the falling prices caused by increased production take place without a fall in the rate of profit. The explanation is that the only fall in the rate of profit that is present is a one-time fall, resulting from the fall in the rate of net consumption from an initial level of $\frac{200}{1,800}$ in *Year 1* to $\frac{100}{1,900}$ in *Year 2* and thereafter, that is, from 11.11 percent to 5.26 percent. (In *Year 2*, this fall in the rate of net consumption is accompanied by the existence of 100 of net investment. Thus, the fall in the rate of profit to 5.26 percent does not take place until *Year 3*, with the disappearance of net investment.⁴)

The one-time fall in the rate of net consumption is the foundation of a *permanent* rise in the relative production of capital goods to a level sufficient to achieve capital accumulation. Once the initial increase in the supply of capital goods is achieved in *Year 2*, on the basis of this rise in their relative production, *further increases in the supply of capital goods take place on the basis of the increased productive ability bestowed by the existence of a larger supply of capital goods in the current year compared with the year before*. Thus a continually growing relative demand for and production of capital goods, and the continually falling rate of net consumption (and thus rate of profit) that would achieve them, are not required for capital accumulation. On the contrary, the larger supply of capital goods in *Year 2* than in *Year 1* all by itself makes possible a larger supply of capital goods in *Year 3* than in *Year 2*, and the same holds true *mutatis mutandis* in all subsequent years.

This is because all by itself the larger supply of capital goods in *Year 2* than in *Year 1* enlarges the total productive power of *Year 2* as compared with *Year 1*. And thus, with the same relatively greater concentration on the production of capital goods, namely, the $\frac{60}{40}$ ratio, the greater productive power of *Year 2* as compared with *Year 1* results in a larger supply of capital goods as well as consumers' goods becoming available in *Year 3* as compared with *Year 2*. In exactly the same way, the larger supply of capital goods in *Year 3* as compared with *Year 2* increases the total productive power of *Year 3* as compared with *Year 2*. The result of the application of this larger total productive power in the same higher ratio, namely, $\frac{60}{40}$, results in a correspondingly larger supply of capital goods as well as consumers' goods in *Year 4* as compared with *Year 3*. And so on, indefinitely, with each year's larger supply of capital goods as compared with the year before, serving to increase its total productive power as compared with the year before and thus, so long as a sufficiently high relative production of capital goods continues, to further increase the supply of capital goods available in the following year.

As explained in Chapter 14, in order for capital accumulation to continue on the foundation of prior increases in the supply of capital goods, technological progress is necessary. But granted that it is present, capital accumulation continues without any further necessary connection to a fall in the rate of profit. Indeed, Figure 17–1 implies that any further fall in the rate of profit would be the result not of capital accumulation, but of factors working to bring about an *acceleration* of the rate of capital accumulation—namely, a further fall in the rate of net consumption and corresponding further increase in the relative demand for and production of capital goods.

For example, an acceleration of capital accumulation would be the result of a further fall in net consumption from 100 to 50, and corresponding further rise in the production of capital goods relative to consumers' goods to a 65:35 ratio, reflecting a 650-demand for capital goods and a 350-demand for consumers' goods. In these circumstances, the supply of capital goods and the ability to produce would increase at a 30 percent annual rate instead of a 20 percent annual rate.⁵

To be sure, if technological progress does not take place, capital accumulation cannot continue in this way. But no significant capital accumulation could then be accomplished in any case, no matter how much the rate of net consumption and the rate of profit might fall. As we have seen, in the absence of technological progress over the course of the last two centuries, no great increase in the supply of capital goods could have occurred—period. As explained in Chapter 14, an economy whose technological limits are described by sailing ships, ox-carts, and forges is simply incapable of accumulating the kind of capital that can be accumulated only on the basis of railroads and steel mills, and then airplanes and petrochemical plants, and the continuing technological progress that all these goods presuppose.⁶

Figure 17–1 makes it possible to understand the error of the economists who believe that capital accumulation implies a falling rate of profit. The error consists, at least in part, of thinking only of what is necessary to bring about the *first* accumulation of additional capital goods in an economy that up to that point has been stationary, and then failing to consider what the effect will be of the possession of those additional capital goods on the subsequent ability to produce capital goods.

This failure to consider the consequences of the possession of more capital goods on the production of capital goods is the result of the habit of most economists of focusing almost exclusively on the production of consumers' goods, as though all that were produced were consumers' goods, and as though capital goods came into existence only by the allegedly very different and unrelated process of saving.⁷ As I have previously explained, this very bad habit is a result of all the utterly confused notions about aggregate production and aggregate spending that I refuted in Chapter 15, notions which imply that aggregate production and aggregate spending are essentially coextensive with the production of and demand for consumers' goods alone.⁸ This mistaken constellation of ideas leads most economists to believe in effect that all capital accumulation must take place in the same way as it does in *Year 2*, that is, on the basis of greater saving in the context of an invariable money and thus on the basis of an increase in the demand for capital goods relative to the demand for consumers' goods. If that were in fact the

only way in which capital accumulation could occur, capital accumulation would imply a falling rate of profit, because then it would almost certainly imply a falling rate of net consumption.⁹

That most economists mistakenly believe this is the only way in which capital accumulation occurs is implicit in their assuming that capital accumulation takes place only by virtue of an act of saving in conditions in which all other things are equal. The condition "all other things equal" includes the demand for and supply of money—that is, it necessarily implies the existence of an invariable money. Repeated acts of saving under an invariable money *would* result in a falling rate of profit. But, as we know, such acts of saving are unnecessary. Each act of saving in such conditions stands in the same relation to capital accumulation as does force to the acceleration of mass in the world of physics. Most economists are unaware of this because they do not carry their analysis to the point of seeing what the effect of the additional capital goods accumulated on the basis of saving is on the further production and supply of capital goods. They do not do this because they do not even stop to realize that capital goods are used to produce capital goods. And they do not do this, in turn, because they are blinded by the mistaken belief that the only goods which are produced are consumers' goods, whose production allegedly "counts" the total of production, and that it is "double counting" to consider the production of capital goods separately.

Apart from the above constellation of errors, the notion that capital accumulation implies a falling rate of profit is probably the result of nothing more than the fallacy of composition, as described in connection with the discussion of Say's Law and the consequences of *relative* overinvestment.¹⁰ Here, the fact that the rate of profit earned in any given industry falls insofar as additional capital investment in it takes place *relative to the rest of the economic system*, is mistakenly taken as the basis for assuming that additional capital investment in the economic system as a whole reduces the general rate of profit.

The explanation of the ability of prices to fall without the rate of profit being reduced is first of all the fact that what determines the rate of profit under the conditions of an invariable money is the rate of net consumption. So long as the rate of net consumption is the same, then—apart from the temporary role played by net investment—the rate of profit is the same. The fact that production increases and prices fall implies nothing whatever about the rate of profit. In such circumstances, precisely as Figure 17–1 makes it possible to see, *an increase in the supply of products is preceded by an equivalent increase*

in the supply and or productivity of the factors of production used to produce them. This prior equivalent increase in the supply and or productivity of the factors of production implies *an equivalent and prior reduction in the average unit costs of production,* with the result that when prices fall because of an increase in production, there is no reduction in the rate of profit.

Thus, for example, the supply of products available for sale at the beginning of *Year 4* increases in the ratio of 6 to 5 over the supply available at the beginning of *Year 3*. That is, in *Year 4* it is 1.728K of capital goods versus the 1.44K of capital goods of *Year 3*, which is an increase of 20 percent, and 1.115C of consumers' goods versus the .96C of consumers' goods of *Year 3*, which is also an increase of 20 percent. Given that the respective demands for capital goods and consumers' goods remain fixed at 600 and 400 monetary units respectively, the inescapable inference is that prices fall in the inverse proportion of 5 to 6. However, it can be clearly seen in Figure 17-1 that this fall in prices does not represent any fall whatsoever in the rate of profit in *Year 4* in comparison with *Year 3*. The rate of profit in both years is 5.26 percent, reflecting 100 of net consumption, and thus 100 of profit, divided by 1,900 of capital.

What happens, as the necessary accompaniment of the increase in production in conditions of an invariable money and a constant rate of net consumption, is that the 20 percent larger supply of capital goods and consumers' goods in *Year 4* in comparison with *Year 3*, is the result of a *preceding* 20 percent larger supply of capital goods in *Year 3* in comparison with *Year 2*, and a preceding 20 percent increase in the productivity of labor. That preceding increase in the supply of capital goods (namely, the 1.44K of capital goods of *Year 3* versus the 1.2K of capital goods of *Year 2*) coming in the face of a fixed 600 monetary units of demand for capital goods, implies a preceding fall—back in *Year 3*—in the prices of capital goods in the ratio of 5 to 6, the same ratio by which the prices of capital goods and consumers' goods now fall in *Year 4*. For the rest, the ability of the same *IL* of labor to produce a 20 percent larger supply of goods for sale at the beginning of *Year 4* in comparison with the supply available at the beginning of *Year 3* implies a 20 percent rise in the average productivity of labor in *Year 3* in comparison with *Year 2*, and thus an inversely proportionate fall in unit labor costs in *Year 3* in comparison with *Year 2*. The reason that unit labor costs fall in this way, is that a rise in the productivity of labor always implies an inversely proportionate fall in the quantity of labor required to produce a unit of product. If the productivity of labor increases by 20 percent—that is, if the same quantity of labor now can produce six-fifths the output as before—the consequence is that the quantity of

labor required to produce any given unit of output is now on average only five-sixths as great as before. And thus, as is the case in Figure 17-1, with the same total wages—300 monetary units—paid to the same total quantity of labor—*IL*—and thus unchanged average wage rates, unit labor costs fall to five-sixths of their previous level. Unit labor costs, of course, are nothing but the product of wage rates times the required quantity of labor. With average wage rates the same and the required quantity of labor per unit only five-sixths as great, unit labor costs are five-sixths as great.

Thus, the fall in prices in *Year 4* is preceded by a fully equivalent fall in average unit costs of production: both costs on account of capital goods—whose prices fall in the same proportion as the prices of the products they help to produce, and fall first—and costs on account of labor—whose productivity rises in proportion to the larger supply of products it helps to produce, and whose cost per unit of product therefore also falls in the same proportion as the selling prices of the products, and falls first.

Despite the fact that average profit per unit also falls—viz., in the same proportion as the price and unit cost—the result is, of course, that the aggregate amount of profit remains the same. This is because the fall in average profit per unit is precisely offset by the increase in production and supply that causes it and that at the same time is in inverse proportion to it. The result of this is that when the reduced average profit per unit is multiplied by the inversely proportionate larger number of units, the aggregate amount of profit is the same.

And so things can continue in *Year 5* and all the other subsequent years, which lack of space makes it impossible actually to show in Figure 17-1. In each year, prices, unit costs, and profits per unit all fall in the ratio of 5 to 6, and, because this is the result of production and supply increasing in the ratio of 6 to 5, the respective arithmetical products of these quantities times the quantity of goods produced and sold—namely, aggregate sales revenues, aggregate costs, and aggregate profits—always remain constant.

Indeed, the fixity of aggregate sales revenues and aggregate costs is the starting point of analysis in most of Figure 17-1, and the constancy of aggregate profit is directly derivable from their fixity. (It is, of course, simply the difference between them.) It is their fixity that accounts for the fall in prices, unit costs, and profits per unit always being in inverse proportion to changes in production and supply, so long as their fixity continues.

It is implicit in the preceding discussion, that nothing whatever depends on any constant rate of increase in production being maintained. It will *always* work out that the fall in cost per unit—both labor cost per unit and

capital-goods cost per unit—will be in proportion to the fall in prices and, of course, will precede the fall in prices inasmuch as the sums giving rise to the costs are expended prior to the receipt of the sales revenues. Thus, if it had happened, for example, that the increase in supply at the beginning of *Year 4* in comparison with *Year 3* had been only 10 percent instead of 20 percent, that is, that the production of *Year 3* had been in the ratio of 11 to 10 to that of *Year 2*, rather than 6 to 5, then the fall in prices in *Year 4* would have been in the ratio of 10 to 11, instead of 5 to 6.

At the same time, in the face of this lesser increase in output relative to the same quantity of labor, the rise in the productivity of labor in *Year 3* in comparison with *Year 2* would also have been only 10 percent. Thus the fall in unit labor costs would have been in the correspondingly lower ratio of 10 to 11, just as the fall in prices. For now ten-elevenths rather than five-sixths of the previous quantity of labor would have been required to produce any given unit of output, and thus with the same average wage rates (resulting from the constancy of the demand for labor at 300 monetary units and of the supply of labor at *IL*), unit labor costs would have been reduced to this, more limited extent.

By the same token, the 20 percent larger supply of capital goods in *Year 3* in comparison with *Year 2* would have had to be employed with a diminished productivity to result in an increase in output of only 10 percent. The corollary of this diminished productivity of capital goods is a corresponding increase in the quantity of capital goods employed per unit of product. Specifically, if six-fifths the capital goods result in the production of only eleven-tenths the output, it follows both that the output per unit of capital goods has fallen in the ratio of 11 to 12 and that the quantity of capital goods required per unit of output has risen in the inverse ratio of 12 to 11. (A rise in output in the ratio of 11:10, divided by the preceding increase in the supply of capital goods in the ratio of 6:5, implies an output per unit of capital goods of 55:60, which, of course, reduces to 11:12. When the output per unit of capital goods is only eleven-twelfths, twelve-elevenths is the quantity of capital goods required to produce the average unit of output.) Twelve-elevenths the quantity of capital goods per unit of output times five-sixths the prices of capital goods is sixty-sixths, which reduces to ten-elevenths. This is the reduction in the capital-goods cost per unit of output, i.e., the same as the reduction in the price of the product.

In exactly the same way, if the increase in production and supply in *Year 4* in comparison with *Year 3* had been more than 20 percent, the correspondingly greater fall in prices would have been accompanied by a correspondingly greater productivity of labor and productivity of

capital goods, which would have resulted once again in unit costs of production falling to the same extent as selling prices, and falling first.

Thus, the principle here is that the fall in prices and the prior fall in unit costs must always be in the same proportion, when a larger output is sold for a given amount of sales revenues and is produced on the basis of a given outlay of money for factors of production. Selling prices fall because of the division of a constant amount of sales revenues by a larger output. Unit costs fall to precisely the same extent, because of the division of a constant amount of expenditure for factors of production by that *same* larger output. In terms of Figure 17–1, the relationships are that the price level of any given year equals 1,000 of sales revenues divided by the total output of the year before, which constitutes the supply available for sale at the start of the current year. The unit-cost level of any given year equals 900 of productive expenditure from the year before, divided by that same output. Thus, the more rapidly output increases, the lower becomes the price and unit-cost levels in precisely the same proportion. Aggregate profit meanwhile always remains at $1,000 - 900$, that is, at 100, and the average rate of profit at $100/1,900$.¹¹

In the context of Figure 17–1, of course, the productive expenditure of any year shows up as the next year's total costs of production. But the equality of productive expenditure and costs of production does not depend on this. As has been shown, under an invariable money, it tends to exist no matter how the productive expenditures of any given year are distributed with respect to production for future years. Productive expenditure and costs *always* tend toward equality, so long as the quantity of money and volume of spending in the economic system remain the same.¹²

Thus, the rate of profit is totally unaffected by the mere rate of increase in physical production and corresponding rate of fall in prices. So long as sales revenues, productive expenditure, and the amount of capital invested stay the same, the amount and rate of profit remain the same, no matter how rapidly production increases and prices fall. For it is then always merely a question of dividing two unequal expenditures or demands—viz., the demand for products, which constitutes sales revenues, and the demand for factors of production, which constitutes productive expenditure and gives rise to equivalent costs—by more rapidly growing denominators. No matter how rapid the growth in these “supply denominators,” so to speak, and no matter how rapid the fall in prices, there is no effect on the amount of profit, which is the difference between the two “demand numerators,” to coin another expression. And so long as the amount of capital invested is the same, there can also be no differ-

ence in the average rate of profit.¹³

Once again, in terms of Figure 17–1, the relationships are that the price level of any given year equals 1,000 of sales revenues divided by the total output of the year before—which is the supply of goods available for sale at the start of the current year—while the unit-cost level equals 900 of productive expenditure from the year before, divided by that same total output. The more rapidly output increases, the lower become the price and unit-cost levels in precisely the same proportion, for all that is reflected is the division of 1,000 and 900 by a denominator that is increased in the same proportion in both instances and, indeed, is always exactly the same in both instances. Aggregate profit meanwhile always remains at $1,000 - 900$. In sum, where S represents aggregate output (the output of capital goods and consumers' goods together), the general price level equals $1,000/S$, the unit-cost level equals $900/S$, and aggregate profit equals $1,000 - 900$. The principle, to say it yet again, in somewhat different words, is that profit depends on the difference between the demand numerators, not on the relationship between one of the demand numerators and its supply denominator. That is, profit depends on the difference between the demand for the products of business and the demand for factors of production by business, on sales revenues minus productive expenditure—in a word, on net consumption—not on prices or the change in prices.

Observe that the only fall in the rate of profit implied by Figure 17–1 occurs in *Year 3*, and that it occurs not as the result of any increase in production and consequent fall in prices, but as the result of the preceding fall in the rate of net consumption and the subsequent elimination of the net investment that took place on the basis of the fall in net consumption. Furthermore, even that one-time fall in the rate of profit, which, it cannot be repeated too often, is in no way caused by the increase in production and fall in prices, would in no way be diminished by any lesser rate of increase in production and fall in prices. If somehow the supply of goods in *Year 3* had not increased over the supply in *Year 2*, prices would not have fallen in *Year 3*. But the fall in the rate of profit would have been exactly the same. The situation then would merely have been that instead of $1.44K$ of capital goods and $.96C$ of consumers' goods having been produced for outlays of 540 and 360 units of money respectively, only $1.2K$ of capital goods and $.8C$ of consumers' goods would have been produced for the same outlays. The result would have been exactly the same rise in aggregate costs and fall in the amount and rate of profit but no increase in production or fall in prices, and, of course, no fall in unit costs of production.

Confirmation of Fact That Falling Prices Caused by Increased Production Do Not Constitute Deflation

The present analysis constitutes a full confirmation of the conclusion reached in Chapter 13 that falling prices caused by increased production do not constitute deflation.¹⁴ Such falling prices do not reduce the average rate of profit. Furthermore, inasmuch as in the nature of the case the average seller must have a supply of goods to sell that is as much enlarged as prices are lower, it follows that there is no greater difficulty entailed in earning any given sum of money at the lower prices that prevail later on than at the higher prices that prevailed earlier. Thus, there is nothing present in falling prices caused by increased production that would make the repayment of debt any more difficult.

The only possible associated element which could temporarily make the repayment of debt more difficult is the fall in the rate of net consumption that results in a corresponding one-time reduction in the rate of profit at the same time that it inaugurates the increase in production and fall in prices. In Figure 17–1, this is the fall in the rate of net consumption that takes place in *Year 2* and which lowers the rate of profit in *Year 3*. If interest rates on loans had not been reduced in anticipation of this fall in the rate of profit, repayment of debt would be rendered more difficult until they were. But, as just shown, even this would not be the result of the increase in production and fall in prices and would not be helped in any way if the increase in production and fall in prices were less or altogether nonexistent. It would be strictly the result of the one-time, delimited fall in the rate of net consumption and thus in the rate of profit.

In fact, however, it is likely that in the period of transition to a lower rate of profit, the rate of interest would fall pretty much in pace with the rate of profit, if not in advance of the fall in the rate of profit. For one thing, in reality the fall in the rate of profit resulting from a fall in the rate of net consumption would not be sudden and precipitous, as it is in Figure 17–1. A more or less extended period of time would exist during which net investment would take place, which would both increase the degree of capital intensiveness in the economic system and to a greater or lesser extent offset the fall in the rate of net consumption. And the fall in the rate of net consumption itself would likely be slow and gradual rather than occur all at once in a single year. Thus the decline in the rate of profit would be gradual. As the rate of profit fell, it would be accompanied by a gradual fall in the rate of interest.

In addition, the very fact that the process is the result of a decline in the rate of net consumption and corresponding rise in saving operates to reduce the rate of interest immediately. This is because the rate of interest

falls as soon as additional savings appear on the loan market in the face of the prevailing initial rate of profit. Because of this, it is probable that the fall in the rate of interest would actually precede the fall in the rate of profit, which, of course, for its part, would be delayed insofar as net investment went on. In addition, the declining rate of interest would give rise to numerous refinancings, thereby tending to reduce the burden of interest payments throughout the economic system. Thus, in the case of a fall in the rate of profit caused by a fall in the rate of net consumption, there would be no sudden plunge in the rate of profit in the face of a large volume of contractually fixed interest rates geared to a substantially higher rate of profit, which is what occurs in a period of deflation or financial contraction.

Indeed, the very fact that a fall in the rate of net consumption entails a rise in saving and productive expenditure, extensive net investment and the formation of new capital giving rise to a higher degree of capital intensiveness, and makes possible a correspondingly greater availability of credit, characterizes it as the very opposite of a period of deflation or financial contraction. In a deflation or financial contraction, productive expenditure falls, net investment becomes negative, capital values decline, and credit becomes largely unobtainable.

Furthermore, looking now at matters over the longer term, once we recall that a by-product of a growing ability to produce is a growing quantity of commodity money, and the effect on the rate of profit of increases in the quantity of money, it becomes obvious that the falling prices resulting from increasing production are almost certain to be accompanied by *a positive addition to the rate of profit*. They are also almost certain to be accompanied by a growing ability to repay debt, because of the growing volume of sales revenues taken in by the average seller as the result of the increasing quantity of money.¹⁵ It should always be kept in mind that in the context of economic progress under a system of commodity money, the fall in prices is the result of a combination of circumstances in which there is an increase in money and spending, but in which the increase in production and supply outstrips the increase in money and spending.

At the same time, of course, it also becomes obvious that the fall in the rate of profit that is the accompaniment of launching or accelerating the process of capital accumulation by means of a fall in the rate of net consumption, is in part reversed by that same positive addition to the rate of profit that accompanies increasing production and its by-product an increasing quantity of commodity money. This is because the increasing production and its monetary by-product are the result of the capital accumulation launched by the fall in the rate of net consumption.

More on the Relationship Between Technological Progress and the Rate of Profit

Observe that Figure 17–1 also fully confirms the discussion in Chapter 13 concerning the alleged effects of technological progress on the rate of profit. It makes it possible to see that technological progress does not raise the rate of profit by “increasing the demand for capital,” but rather prevents the fall in prices caused by increasing production from lowering the rate of profit. This is because the actual effect of technological progress is, along with increasing the supply of consumers’ goods, to increase the supply and lower the prices of capital goods and to raise the productivity of labor, both of which, as shown, cause unit costs to fall to the same extent as prices and to do so prior to the fall in prices, so that when prices fall there is no fall in the amount or rate of profit. Indeed, it is only by virtue of increasing the supply of capital goods and/or the productivity of labor that technological progress serves to increase the supply of consumers’ goods. And thus the fall in the prices of consumers’ goods that technological progress is undeniably accountable for is inseparably connected with a preceding fall in the unit costs of production, for which technological progress bears equal responsibility.¹⁶

The only positive connection between technological progress and the rate of profit is by way of the increase in the quantity of commodity money that is the by-product of a growing ability to produce. Insofar as technological progress underlies a growing ability to produce, and thus a growing quantity of commodity money, it is indirectly the source of an addition to the rate of profit, namely, of the monetary component in the rate of profit. Furthermore, insofar as this monetary component is at the same time the net investment component in the rate of profit, technological progress may be said to be the indirect source of net investment and the net investment component in the rate of profit.¹⁷

This last connection is doubly ironic when understood against the backdrop of the prevailing Keynesian fallacies, which regard net investment not only as in no way based on technological progress, but also as requiring technological progress to offset its allegedly negative effects on the rate of profit. The double irony is the fact that the only way in which technological progress does contribute to the rate of profit is precisely in its capacity *as the source of net investment*, which, far from reducing the rate of profit, represents a major component of the rate of profit. Just as technological progress is not required as an “outlet” for capital goods accumulated merely by means of saving, but is itself the source of capital goods, so in its relation to the increase in the supply of commodity money it is not an outlet for net investment, but is itself the source of net investment. And

this net investment, through the contribution it makes to the rate of profit, can in turn be described as providing its own outlet for profitable investment.

Ricardo's Insights on Capital Accumulation

The fundamental relationship between technological progress and increases in production, on the one side, and the rate of profit, on the other, is clearly understood by Ricardo, who writes:

The rate of profits is never increased by a better distribution of labour, by the invention of machinery, by the establishment of roads and canals, or by any means of abridging labour either in the manufacture or in the conveyance of goods. These are causes which operate on price, and never fail to be highly beneficial to consumers; since they enable them with the same labour, or with the value of the same labour, to obtain in exchange a greater quantity of the commodity to which the improvement is applied; but they have no effect whatever on profit.¹⁸

Ricardo, of course, writes in the context of an invariable money, which for him signifies the employment of the same total quantity of labor in the economic system, while for us it means the expenditure of the same total amount of money to buy newly produced goods. And, of course, he refers to the general or average rate of profit, not to the particular rates of profit of innovators or of those who must compete against the innovators. As we know, technological progress increases the profits of the innovators and decreases the profits of those against whom the innovators compete. What it does not do is raise the general or average rate of profit—the rate of profit that is earned taking innovators and laggards together—except, of course, to the extent that it results in an increase in the supply of commodity money and thus in the volume of spending in the economic system.

With no less remarkable insight, Ricardo implicitly grasps the role of technological progress in capital accumulation and sees that in the context of an invariable money, capital can be accumulated without continuous acts of saving, that is, without continuous increases in productive expenditure and the demand for capital goods relative to the demand for consumers' goods. In his chapter "Value and Riches, Their Distinctive Properties," he declares:

From what has been said, it will be seen that the wealth of a country may be increased in two ways: it may be increased by employing a greater portion of revenue in the maintenance of productive labour, which will not only add to the quantity, but to the value of the mass of commodities; or it may be increased without employing any additional quantity of labour, by making the same quantity more productive, which will add to the abundance, but not to the value of commodities.

In the first case, a country would not only become rich,

but the value of its riches would increase. It would become rich by parsimony—by diminishing its expenditure on objects of luxury and enjoyment, and employing those savings in reproduction.

In the second case, there will not necessarily be either any diminished expenditure on luxuries and enjoyments, or any increased quantity of productive labour employed, but, with the same labour, more would be produced; wealth would increase, but not value. Of these two modes of increasing wealth, the last must be preferred, since it produces the same effect without the privation and diminution of enjoyments which can never fail to accompany the first mode. Capital is that part of the wealth of a country which is employed with a view to future production, and may be increased in the same manner as wealth. An additional capital will be equally efficacious in the production of future wealth, whether it be obtained from improvements in skill and machinery [viz., technological progress and or a larger previous supply of capital goods], or from using more revenue reproductively [viz, saving]; for wealth always depends on the quantity of commodities produced, without any regard to the facility with which the instruments employed in production may have been procured.¹⁹

All one need do to make these passages fully accord with the views I have been propounding is to substitute for the fixity of the quantity of labor as the basis of an invariable money, the fixity of the quantity of money itself and thus of the total volume of spending to buy newly produced goods. Then it is clear that in such a context, saving—viz., a fall in consumption expenditure and rise in productive expenditure—represents an increase in the monetary value of the capital employed in production, and, if productive expenditure remains at the higher level, an increase in the total cost-value of commodities. This is the way capital accumulation begins in Figure 17–1, when net consumption falls from 200 monetary units to 100 and the rise in productive expenditure increases the cost value of output from 800 to 900 monetary units. It is also clear that capital accumulation can take place without further such saving, as the rest of Figure 17–1 shows. Indeed, Ricardo argued that it is even possible for capital accumulation to take place in the face of *smaller* aggregate value of capital—in the face of a smaller relative production of capital goods. He writes in his chapter "On Wages":

Or capital may increase without its value increasing, and even while its value is actually diminishing. . . the addition may be made by the aid of machinery, without any increase, and even with an absolute diminution in the proportional quantity of labor required to produce [the goods constituting capital]. The quantity of capital may increase, while neither the whole together, nor any part of it singly, will have a greater value than before, but may actually have a less.²⁰

Such a situation can be imagined in terms of the

economic system shifting from the conditions of Figure 17–1 to conditions somewhere between those of Figure 17–1 and those of Figure 16–2. In such an intermediate situation, represented, for example, by the demand for capital goods being 550 instead of 600, and total productive expenditure being 850 instead of 900, capital accumulation would continue, though at a less rapid rate than in Figure 17–1. It would be accompanied by a reduction in the total value of accumulated capital and in the total cost value of the output produced. It would also be accompanied by a rise in the amount and rate of profit.

As the next section of this chapter will show, however, there are more or less strict limits to the extent to which capital accumulation is possible in the face of a fall in productive expenditure and the relative demand for capital goods, and thus to the case Ricardo describes. This is because the ability to implement technological advances vitally depends on the relative production of capital goods.²¹

The Rate of Profit and the Demand for Money

Preceding discussion has shown repeatedly that as far as the rate of profit is concerned, there is a fundamental distinction between falling prices caused by increasing production and falling prices caused by a falling quantity of money and volume of spending. Essentially, only the latter is associated with a fall in the rate of profit. The former is not.²²

It is also necessary to realize that there is a fundamental distinction with respect to the effect on *the demand for money for holding*, between a fall in the rate of profit caused by a fall in the quantity of money and volume of spending—i.e., deflation—and a fall in the rate of profit caused by a fall in the rate of net consumption. Only the former operates to raise the demand for money for holding. The latter does not.

There are two reasons for this. First, unlike a fall in the quantity of money and volume of spending, a fall in the rate of net consumption cannot render the rate of profit negative. At most, it can only reduce the rate of profit to a lower positive number.²³ Second, as we have seen, in the nature of the case, a fall in the rate of profit caused by a fall in the rate of net consumption is accompanied by an increase in the supply of savings and thus an increase in the availability of credit.²⁴ As I showed in Chapter 12, a greater supply of savings and a consequent greater availability of credit operate to reduce the demand for money for holding. It follows that in such an environment, any tendency of a lower rate of return on capital to increase the demand for money for holding, by virtue of reducing the advantages of investing in comparison with holding cash, is necessarily accompanied by off-

setting factors that work in the opposite direction.²⁵

Of course, beyond this, a fall in the rate of net consumption is virtually certain to result in a less than equivalent fall in the rate of profit, because of its indirect effects on the rate of increase in the supply of a commodity money, as we have also seen.²⁶ Finally, as I will show later in this chapter, the effect of any increase in the demand for money for holding that for any reason might occur is ultimately to raise the rate of net consumption and rate of profit.²⁷

3. Why Capital Accumulation Does Not Depend on a Continuous Lengthening of the Average Period of Production

The analysis of Figure 17–1 has shown conclusively that neither capital accumulation nor falling prices caused by increased production imply a falling rate of profit or wiping out of profit or are in any way “deflationary.”

Essentially the same analysis demonstrates the error of believing that capital accumulation implies a continuous lengthening of the average period of production or structure of production. Both of these concepts, which mean essentially the same thing, can be expressed in terms of the differing conditions of Figures 16–2 and 17–1.

In Figure 16–2, 50 percent of the capital goods and labor of each year are used in producing consumers’ goods for the following year, and the remaining 50 percent, in producing capital goods for the following year. Inasmuch as the capital goods of the following year are in turn themselves used 50 percent to produce consumers’ goods for the year after that, it follows that of the half of the labor and capital goods used in any given year to produce capital goods for the following year, half of that half, or 25 percent, indirectly serves in the production of consumers’ goods in the year following the following year, that is, in the year after next. The implication of this is that by the end of *two* years, 75 percent of the capital goods and labor in existence in any year will have ended up directly or indirectly serving in the production of consumers’ goods—50 percent in the production of the consumers’ goods of the following year, and 25 percent in the production of the consumers’ goods of the year after that.

By an extension of the same reasoning, it further follows that by the end of three years, the cumulative proportion of capital goods and labor in existence in any given year that will have ended up directly or indirectly serving in the production of consumers’ goods will be 87.5 percent, and so on. This is because the capital goods in existence in the year after next and which reflect the remaining 25 percent of the labor and capital goods of

Figure 17-2

The Average Period of Production Under a 50% Relative Production of Capital Goods

two years earlier that has not yet contributed to the production of consumers' goods, are now used 50 percent in the production of consumers' goods of three years later.²⁸

The cumulative increase in the proportion of the capital goods and labor of any given base year that directly or indirectly serves in the production of consumers' goods is clearly indicated in Figure 17-2, which superimposes on Figure 16-2 the connections between the supply of labor and capital goods in a given base year and the supplies of consumers' goods and capital goods of various future years. Figure 17-2 takes *Year 1* as the base year and shows the extent to which the capital goods and labor of that year not only directly serve in the production of capital goods and consumers' goods for the following year, but also indirectly serve in the production of capital goods and consumers' goods that become available at the beginning of *Years 3* and *4*.

The figure shows 25 percent of the capital goods and labor of *Year 1* indirectly serving in the production of the capital goods of *Year 3*, and 25 percent indirectly serving in the production of the consumers' goods of *Year 3*. These percentages reflect the fact that 50 percent of the capital goods and labor of *Year 1* are used up in producing the capital goods of *Year 2*, of which, in turn, 50 percent are used up in producing the capital goods of *Year 3*, and 50 percent in producing the consumers' goods of *Year 3*. (In both cases, 50 percent of 50 percent yields an indirect contribution of 25 percent.) The fact that 25 percent of the capital goods and labor of *Year 1* thus indirectly serve in producing the capital goods available at the start of *Year 3* and that these capital goods, in their turn, are used up 50 percent in the production of the capital goods that will become available at the start of *Year 4* and 50 percent in the production of the consumers' goods that will become available at the start of *Year 4*, underlies the further fact that 12.5 percent of the capital goods and labor of *Year 1* indirectly serve in producing the capital goods of *Year 4* and 12.5 percent indirectly serve in producing the consumers' goods of *Year 4*.

In this way, with the passage of years, the cumulative proportion of the capital goods and labor in existence in any base year that directly or indirectly serves in the production of consumers' goods continually grows, while the proportion continuing to serve indirectly in the production of capital goods and thus of consumers' goods in the still further future continually declines.

One can express the concept of the average period of production or the length of the structure of production in terms of how many years must elapse before some given percentage of the capital goods and labor in existence in a base year will have ended up directly or indirectly serving in the production of consumers' goods. If that

given percentage is taken as 90 percent, then the length of the average period or structure of production in the conditions of Figure 16-2 is obviously somewhere between three and four years, for in three years 87.5 percent of the capital goods and labor in existence in a base year will have ended up directly or indirectly serving in the production of consumers' goods, while at the end of four years, the figure will be 93.75 percent—viz., 87.5 percent plus 50 percent of 12.5 percent, which, of course, is 6.25 percent.

Proceeding now in the same way in the conditions of Figure 17-1 (which are reproduced in Figure 17-3), it is clear that here the length of the average period or structure of production is somewhat greater. Figure 17-3 superimposes on Figure 17-1 the connections between the supply of labor and capital goods in a given base year—once again *Year 1* has been chosen for this purpose—and various future years. It shows the indirect contribution of the capital goods and labor of *Year 1* to the capital goods and consumers' goods available at the start of *Years 3* and *4* in the conditions of the higher relative production of capital goods that prevails in Figure 17-1.

Because 60 percent of the capital goods and labor of *Year 1* are used to produce the capital goods of *Year 2*, 60 percent of which are used up in producing the capital goods of *Year 3* and 40 percent of which are used up in producing the consumers' goods of *Year 3*, the capital goods and labor of *Year 1* indirectly serve 36 percent in the production of the capital goods of *Year 3* (.6 x .6) and 24 percent in the production of the consumers' goods of *Year 3* (.4 x .6). Because the capital goods of *Year 3* in turn are used up 60 percent in the production of further capital goods and 40 percent in the production of consumers' goods, the further indirect contribution of the capital goods and labor of *Year 1* to the capital goods and consumers' goods of *Year 4* is 21.6 percent (.6 x .36) and 14.4 percent (.4 x 21.6) respectively. For *Year 5* (not shown in the figure), their indirect contribution is 60 percent of the 21.6 percent and 40 percent of the 21.6 percent respectively, viz., 12.96 percent and 8.64 percent respectively.

It follows that the cumulative contribution of the capital goods and labor in existence in a base year to the production of consumers' goods over the following four years, that is, through *Year 5*, will be the sum of .4 + (.4 x .6) + (.4 x .6²) + (.4 x .6³), that is, 87.04 percent. Thus the length of the average period or structure of production in this case is greater than four years, for obviously more than four years must elapse before 90 percent of the capital goods and labor in existence in a base year end up serving directly or indirectly in the production of consumers' goods. In the conditions of Figure 16-2, of

Figure 17-3

The Average Period of Production Under a 60% Relative Production of Capital Goods

course, the cumulative total of 90 percent was reached in less than four years.

Now what is essential for present purposes is merely to realize that while the length of the average period or structure of production in the conditions of Figure 17–1 is greater than in those of Figure 16–2, once that greater length has been established, capital accumulation thereafter proceeds *without any further such lengthening*. A further such lengthening of the average period of production would be identical to a further rise in the *relative production of capital goods*, which, of course, is not necessary to the continuation of capital accumulation, but to its *acceleration*.²⁹

The Average Period of Production and the Limits to Technological Progress as a Source of Capital Accumulation

The concept of the average period of production sheds further light on the necessity of a sufficiently high economic degree of capitalism and degree of capital intensiveness in order for capital accumulation and economic progress to take place. At the same time, it makes clear the limits of technological progress as a source of capital accumulation. The longer is the average period of production, the greater is the foundation on which technological progress can be applied. It can be applied to a correspondingly greater extent in the production of future products requiring temporally more remote applications of existing capital goods and labor and, by the same token, in the production of present products requiring the application of relatively more capital goods and labor existing in past years.

For example, imagine two different economic systems. In one, the average period of production is such that fully 10 percent of the capital goods and labor of any given base year serves in the production of capital goods and consumers' goods that will become available in five years. In the other, the average period of production is such that less than 1 percent of the capital goods and labor of any given base year serves in the production of capital goods and consumers' goods that will become available in five years. It is obvious that technological progress that relates to the kinds of capital goods or consumers' goods specifically requiring productive activity five years in the past will be much more likely to be capable of being implemented in the first economic system than in the second. A concrete example of this might be the construction of such things as factory buildings, bridges, and tunnels with an actual construction time of five years. If hardly any of the capital goods and labor of a given year are devoted to the production of goods that become available five years later, then technological progress in the construction of such things may simply be altogether

incapable of application.

Figures 17–2 and 17–3 can be used as illustrations of the differing extents to which the past can serve the present, as well as the present serve the future. In looking backward from any year, the proportions of the labor and capital goods of past years serving the production of any present year taken as a base are greater in Figure 17–3 than in Figure 17–2, and become relatively greater the more remote are the past years. For example, 60% vs. 50% for one year past; 36% vs. 25% for two years past; 21.6% vs. 12.5% for three years past; 12.96% vs. 6.25% for four years past, and so on. It is possible to implement technological advances in the conditions of Figure 17–3 which it is not possible to implement in the conditions of Figure 17–2, because of this greater contribution of the past to the present, and of the present to the future.³⁰

This discussion, of course, reinforces the conclusions reached earlier about the role of capital intensiveness in determining an economy's ability to implement technological progress.³¹

It should be realized that a more-capital-intensive economic system is at absolutely no disadvantage in comparison with a less-capital-intensive economic system when it comes to implementing technologies requiring less capital intensiveness. The capacity for implementing more-capital-intensive technologies always subsumes the capacity for implementing less-capital-intensive technologies, while the reverse is not the case. It is the same in principle as the fact that a millionaire always has the ability to come down the scale and live like an average person if he wishes, while the average person lacks the ability to go up the scale and live like a millionaire.

For example, an economy that was sufficiently capital intensive to be capable of turning out thirty-year-old scotch for the mass market, would have no difficulty in turning out eight-year-old scotch for whatever part of the market might wish it. However, without greater capital intensiveness in the economic system as a whole, an economy that presently turns out only eight-year-old scotch for the mass market would encounter considerable difficulty in finding the resources to replace the eight-year-old scotch with thirty-year-old scotch.

In the same way that the advantages of living like a millionaire almost always preclude a millionaire's actually living like an average person, so the advantages of greater capital intensiveness, in terms of higher-quality products and lower-cost methods of production, preclude a more-capital-intensive economic system from actually attempting to revert to the products and methods of production of a less-capital-intensive economic system in any but the most exceptional and isolated cases.

4. Implications for the Doctrine of Price Premiums in the Rate of Interest

Recognition of the fact that falling prices caused by increased production do not reduce the rate of profit necessitates a major modification in the important economic doctrine of “purchasing-power-price premiums” in the loan-market rate of interest. According to this doctrine, the anticipation of rising prices adds a corresponding positive component to the loan market rate of interest, while the anticipation of falling prices adds a corresponding negative component to the loan market rate of interest.³² When stated in this form, the doctrine leads to the conclusion that rapid increases in production are potentially capable of wiping out the rate of interest altogether. This is because if the rate of interest were initially 4 percent, say, and production increased by more than 4 percent a year—say, by 5 or 6 percent, with the result that prices fell by approximately 5 or 6 percent—then the doctrine would imply the existence of a negative rate of interest and thus the disappearance of any incentive to lend money rather than hold it. This, in turn, would imply the sudden emergence of a major inducement to hold money that was not present before, and thus the onset of a depression. In other words, rapid increases in production are implied to be capable of causing depressions.

On the basis of the preceding discussion, however, it should be clear that there is no basis for the anticipation of falling prices caused by increased production to result in a reduction in the rate of interest.³³ For I have shown that in the context of an invariable money, where falling prices are caused by increases in production and supply, absolutely no fall whatsoever takes place in the rate of profit as the result of the increase in production and fall in prices. Inasmuch as such falling prices do not reduce the rate of profit, they do not reduce the demand for loanable funds; nor, for the same reason, do they serve as an inducement to the shifting of funds from direct investment to the loan market, and thus they do not increase the supply of loanable funds. Since they neither decrease the demand for loanable funds nor increase the supply of loanable funds, they do not result in a lower rate of interest.

As I have shown, it is not falling prices per se that should be associated with a reduction in the rate of profit and interest, but falling prices *caused by a reduction in the quantity of money and volume of spending*.³⁴ Even this formulation somewhat misses the mark, because the price changes are altogether nonessential. This is because a reduction in the quantity of money and volume of spending reduces the rate of profit and interest even if at the same time prices stay the same, or actually rise.

(Prices would stay the same or rise if production and supply fell to the same extent or a greater extent as the quantity of money and volume of spending.) Deflationary reductions in the rate of profit and interest are thus not a matter of price changes at all, but strictly of changes in the quantity of money and volume of spending.

Exactly the same principles apply to the rise in the rate of profit and interest associated with rising prices: they are due strictly to the increase in the quantity of money and volume of spending and not at all to the rise in prices per se.

Indeed, I have shown that a rising quantity of money and volume of spending act to raise the rate of profit and interest even when the increase in money and spending is relatively modest and is outstripped by the increase in production and supply, with the result that prices fall. By the same token, a falling quantity of money and volume of spending act to reduce the rate of profit and interest even if accompanied by rising prices caused by a fall in production and supply to an extent greater than the fall in the quantity of money and volume of spending. Just as more production and supply do not lower the rate of profit and interest, irrespective of any fall in prices, so less production and supply do not raise the rate of profit or interest, irrespective of any rise in prices.

As I have shown, changes in the price level are related to changes in the rate of profit and interest merely by a process of association. What underlies the association and actually explains the changes in both the price level and the rate of profit and interest is changes in the quantity of money and volume of spending. As the quantity of money and volume of spending increase, prices and the rate of profit and interest tend to increase together. As the quantity of money and volume of spending decrease, prices and the rate of profit and interest tend to decrease together. The essential underlying causal element that creates the association is the change in the quantity of money and volume of spending.

Now insofar as there are changes in the supply of goods produced and sold that take place in the same direction as the changes in the quantity of money and volume of spending, the changes in the price level that would otherwise be caused by the changes in the quantity of money and volume of spending are offset and may, indeed, actually be overcome. But the changes in the nominal rate of profit and interest caused by the changes in the quantity of money and volume of spending remain. Thus, as I demonstrated earlier in this chapter, falling prices caused by increases in production and supply are actually capable of being accompanied by an *increase* in the rate of profit and interest.³⁵ All that is necessary for prices to fall while the rate of profit and interest is increased is that at the same time that production and

supply increase, there is an increase in the quantity of money and volume of spending that is less than the rise in production and supply. In this way, the increase in the quantity of money and volume of spending adds to the rate of profit and interest, but the still greater increase in production and supply overcomes its price-raising effects and succeeds in reducing the price level.

In exactly the same way, rising prices caused by a decrease in production and supply are capable of being accompanied by a decrease in the rate of profit and interest. All that is necessary is that at the same time that the fall in production and supply raises prices, there is a decrease in the quantity of money and volume of spending that is less than the fall in production and supply. In this case, the price-reducing effects of the fall in the quantity of money and volume of spending are more than overcome, with the result that prices rise. But the negative effect of the fall in the quantity of money and volume of spending on the rate of profit and interest remains. Thus, prices rise while the rate of profit and interest is reduced.

The doctrine of the purchasing-power-price premiums is thus substantially mistaken. One should speak instead, of a positive or negative *monetary component* in the rate of profit and interest, reflecting the change in the quantity of money and volume of spending in the economic system. This would permit recognition of the fact that falling prices caused by increased production not only do not reduce the rate of profit and interest but, under a commodity money, are actually almost always accompanied by a positive addition to the rate of profit and interest resulting from the increased production and supply of the monetary commodity or commodities that takes place as a by-product of the general increase in the ability to produce. It would also greatly encourage recognition of the fact that depressions and all their negative consequences are a strictly *monetary* phenomenon, proceeding from a monetary system of a kind which makes possible sudden, large-scale decreases in the quantity of money and sudden, large-scale increases in the demand for money for holding.³⁶

5. Implications for the Process of Raising Real Wages

Figure 17–1 shows the process by which real wages are increased, namely, through an increase in the supply of capital goods relative to the supply of labor, which is then followed by an increase both in the supply of consumers' goods relative to the supply of labor and by a further increase in the supply of capital goods relative to the supply of labor. On this basis, in each year in Figure 17–1, from *Year 3* on and continuing indefinitely, real wages rise, as a steadily growing supply of consumers'

goods is sold for the same 400 monetary units of consumption expenditure while total wage payments remain at 300 monetary units.

The figure makes plain the role of a lower rate of net consumption in inaugurating the rise in real wages and is fully consistent with, if it does not actually suggest, the role of the competitive quest of businessmen and capitalists for above-average profits in the continuation of technological progress, capital accumulation, and rising real wages.³⁷ It shows how rising real wages are possible without any continuing fall in the rate of profit, and how, in fact, the buying power of the constant monetary amount of profits is increased at the same rate as the buying power of the constant monetary amount of wages—in other words, how real profits and real wages increase together. It shows how the process of raising real wages always takes place from the side of production and supply and is fundamentally a process that in the absence of increases in the quantity of money and volume of spending would raise real wages exclusively by means of reducing the prices of the goods purchased by wage earners, not by raising money wages. Of course, along with Figure 16–2, it also makes apparent the role of saving and productive expenditure in determining the demand for labor relative to the demand for consumers' goods. In essence, Figure 17–1 can be taken as a confirmation of the entire productivity theory of wages and its applications, which I presented in Chapter 14.³⁸

6. How the Taxation of Profits Raises the Rate of Profit

The invariable-money/net-consumption analysis leads to the conclusion that the taxation of profit results in a substantially equivalent rise in the pretax amount of profit and in a corresponding rise in the pretax rate of profit.³⁹

The fact that the consumption of businessmen and capitalists is governed primarily by their possession of capital rather than by their earning of income implies that the taxation of profit and interest falls mainly on capital. This is because so long as their capital remains intact, the consumption of businessmen and capitalists is not substantially reduced by the reduction in their disposable income that taxation causes.⁴⁰

It is because the taxation of profit and interest falls mainly on capital, that its long-run effect is to raise the rate of profit and interest on a pretax basis. This comes about because, in falling on capital, the taxation of profit and interest reduces productive expenditure. Funds which business firms would have used for the purchase of machinery and materials and the payment of wages are instead diverted to the payment of taxes. The government, or the people to whom the government gives the

tax proceeds, spend the funds. Thus, the aggregate monetary demand for products as such remains the same. What happens is that the demand for machinery and materials by business falls, the demand for consumers' goods by the employees of business falls (as the result of the fall in the demand for labor by business), but the demand for consumers' goods by the government or those to whom the government gives the tax money rises by an amount equal to these reductions. However, while aggregate sales revenues thus remain the same, the reduction in productive expenditure brings about an equivalent reduction in the aggregate costs of production that are deducted from sales revenues in computing profits. Thus, aggregate profits increase correspondingly.

The rise in aggregate profits, of course, is only on a pretax basis. What occurs, in effect, is that costs in the form of taxes displace normal business costs in the form of costs on account of machinery, materials, and labor. If the taxes are excluded from costs, as they are in calculating profits on a pretax basis, aggregate profits rise by an equivalent amount. They rise to whatever extent tax costs, which are not counted in the computation of pretax profits, displace ordinary business costs, which are counted in the computation of pretax profits.

The process can be understood by using Figure 17-1 as the framework of analysis. From *Year 3* on, the rate of net consumption in Figure 17-1 is implicitly equal to one-twentieth of the sum of the 1,900 of capital plus the annual 100 of profit received by the businessmen and capitalists. (Expressed relative to capital alone, the rate of net consumption is, of course, one-nineteenth.) If in some year subsequent to *Year 3*, the government imposes a tax of, say, 50 percent on profit income, the effect will be to make the net-consumption rate apply to 1,950 of capital-plus-its-income rather than to 2,000 of capital-plus-its-income. Thus the amount of net consumption will fall merely from 100 to 97.5—that is, to $\frac{1}{20} \times 1,950$. As a result, the far greater part of the tax will fall on productive expenditure and capital, which will both decline by 47.5—that is, by the amount of the excess of net consumption of 97.5 over aftertax profits of 50. Productive expenditure and capital will thus fall from 900 and 1,900 respectively to 852.5 and 1,852.5 respectively.⁴¹

Since the drop in productive expenditure will bring about an equivalent drop in aggregate business costs, i.e., to 852.5 from 900, while aggregate sales revenues remain at 1,000, the further effect will be a rise in pretax profits from 100 to 147.5. If the tax rate remains at 50 percent, the process is not yet complete. This is because taxes will now rise from 50 to 73.75 (50 percent of the profit of 147.5). Net consumption will again fall modestly, while productive expenditure and capital bear the brunt of the still higher tax payments. Equilibrium will

be reached only when pretax profits are almost doubled and the aftertax portion of profit becomes high enough to cover the whole of the amount of net consumption dictated by the sum of remaining capital plus the aftertax profit.

Indeed, under the present assumptions, a precise equilibrium will be reached in the conditions of Figure 17-1 only when productive expenditure falls to 809.52, and capital to 1,809.52. At that point, a net-consumption rate of one-twentieth applied to capital-plus-the-aftertax-profit (or, equivalently, a rate of net consumption of one-nineteenth applied to capital alone) results in an aftertax profit of 95.24 and a pretax profit of double that amount, or 190.48. This pretax profit of 190.48 is regenerated in every year by the combined operation of 95.24 of net consumption plus the expenditure of tax proceeds of a further 95.24. Net consumption plus the expenditure of the tax proceeds serve to make sales revenues in every year exceed productive expenditure and thus costs other than taxes by 190.48.

These specific figures are arrived at on the basis that capital in Figure 17-1 equals 1,000 monetary units plus productive expenditure, while, at the same time, in a state of equilibrium, productive expenditure equals 1,000 monetary units of sales revenues minus an amount equal to two times aftertax profit (i.e., the sum of net consumption plus tax payments equal to net consumption), with aftertax profit itself equal to one-twentieth of the sum of capital plus aftertax profit. Thus, where K is capital, B is productive expenditure, and p is profit after tax,

$$(1) \quad K = 1,000 + B,$$

$$(2) \quad B = 1,000 - 2p,$$

and

$$(3) \quad p = (K+p)/20.$$

The solution for equation (3) is obvious:

$$(4) \quad 19p = K.$$

When $19p$ is substituted for K in (1), and (2) is substituted for B in (1), the result is

$$(5) \quad 19p = 1,000 + 1,000 - 2p.$$

Thus,

$$(6) \quad 21p = 2000,$$

and, therefore,

$$(7) \quad p = 95.24.$$

Thus, the effect of the imposition of a 50 percent tax rate on profits is almost equivalent to that of a doubling of the rate of net consumption. In terms of Figures 16-2 and 17-1, it represents driving the economic system back from the progressive conditions of Figure 17-1 toward the stationary conditions of Figure 16-2. In addition, of

course, in real life, the effect would also be to reduce the demand for labor by business relative to the demand for consumers' goods.

Obviously, at some point, the taxation of profits becomes capable of stopping economic progress altogether and causing economic retrogression. At every step of the way, it is diametrically opposed to the real self-interests of the wage earners, because it operates totally counter to the rise in real wages.

Insofar as the rise in aggregate pretax profits is at the expense specifically of the demand for capital goods, not only profit but also national income rises. Indeed, the present case is very similar to the operation of the so-called balanced-budget multiplier and is a further illustration of the inverse relationship that prevails under an invariable money between aggregate profits and money national income, on the one side, and economic progress and prosperity, on the other.⁴²

Insofar as the rise in aggregate pretax profits is at the expense specifically of the demand for labor by business, there is no rise in nominal national income as far as it is generated in business firms. There is merely a displacement of wage payments by tax payments, with the government and those to whom it gives money obtaining funds at the expense of the wage earners. Pretax profits rise simply because the tax payments are not deducted from sales revenues in calculating pretax profits while costs on account of labor, of course, are deducted. As in the case of pretax profits rising at the expense of the demand for capital goods, the rise in pretax profits at the expense of the demand for labor is of absolutely no benefit to business firms. It signifies nothing but that they pay taxes instead of wages. Indeed, in real terms there is almost certainly a loss to business firms—and to the general consuming public, as well—just as there is when taxes rise at the expense of the demand for capital goods. The loss in this case comes about insofar as the government uses the tax proceeds to employ labor and to this extent bids labor away from business firms and thus from the production of goods and services serving the general consuming public.⁴³

The Influence of the Monetary System

It must be pointed out that the rise in aggregate pretax profits does not depend on aggregate costs falling absolutely, as they ultimately would in an economic system with a fixed quantity of money and a fixed aggregate monetary demand. The rise in aggregate pretax profits also occurs insofar as aggregate costs fall in comparison with what they otherwise would have been. In an economic system with an increasing quantity of money and rising aggregate monetary demand, the effect is that the

growth in productive expenditure is less than it otherwise would have been and that productive expenditure comes to stand at any given time at a lower level than it otherwise would have achieved, even if it is able to go on rising. The effect of this, in turn, is that aggregate costs come to stand at a lower level than they would otherwise have reached. Thus, aggregate profit and the average rate of profit, on a pretax basis, are correspondingly increased.

The precise effect of the taxation of profit and interest incomes on the pretax rate of profit depends on the type of monetary system a country has. Under an invariable money or under a fiat money, the effect is clearly a rise, in the ways just explained. Indeed, under a fiat money system, it is almost certain that as a result of its negative effects on capital accumulation and economic progress, a rise in the taxation of profit or interest incomes will be followed by a more rapid rate of increase in the quantity of money and thus by a further, corresponding addition to the rate of profit. This is because the government will be tempted to print money all the more rapidly to the degree that a lesser rate of economic progress—let alone economic stagnation or outright economic retrogression—diminishes the real revenues at its disposal while at the same time increasing the demands made upon it by the public.

Under a commodity money system, on the other hand, reduced capital accumulation and the lesser increases in the ability to produce that it causes result in a reduced rate of increase in the quantity of money in a country. If the reduction in capital accumulation is sufficient to render a country's economic system stationary or, worse still, retrogressive, the country's quantity of money will be likely actually to fall, owing to its declining economic status relative to other countries and its correspondingly declining share of the world's supply of commodity money. (If economic retrogression pervades the world as a whole, the quantity of money will decline owing to a decline in the production of precious metals below the point required for maintenance of the money supply.)

Such effects on the money supply result in a diminution of the monetary component in the rate of profit and could even turn the monetary component negative. Thus, under a commodity money, the taxation of profit and interest income need not result in a rise in the general rate of profit in a country, for the reduction in productive expenditure will be followed by reductions in sales revenues, or, at the least, lesser increases in sales revenues.

Because of the intimate connection between the monetary component of the rate of profit and the net investment component, the reduction or elimination of the former means the reduction or elimination of the latter.⁴⁴ Thus, what happens in the case of a commodity money

is that the effect of a tax on profit or interest is to consume funds that otherwise would have represented net investment and to more or less abort the process that would have led to continuing nominal and real net investment. As a result, under a commodity money, profits corresponding to the taxes on profits for the most part merely take the place of profits corresponding to the increase in the quantity of money and corresponding net investment, and to that extent do not succeed in actually raising the pretax rate of profit. This, of course, operates to limit the extent of the damage that taxes on profits and interest are capable of doing, insofar as it takes away the possibility of their being applied to profits and interest which they themselves call into being.

The clear implication of this section is that a principal means of bringing down the present, very high rate of profit and interest is to reduce government spending and abolish the taxation of profit and interest, and all other taxation which falls on saving and productive expenditure. Such a policy would raise productive expenditure, and ultimately costs, relative to sales revenues, thereby diminishing the amount of profit and interest income in the economic system on a pretax basis. It would also result in a rise in the amount of capital invested, both absolutely and relative to sales revenues, consumption, and wage payments. It would be the basis of a rise in the demand for capital goods relative to consumers' goods, a rise in the demand for labor by business relative to the demand for consumers' goods, and a rise in the degree of capital intensiveness. It would thus be the foundation for an acceleration of capital accumulation and economic progress, not only from a state of less rapid economic progress to more rapid economic progress, but also, and even more importantly, from a state of economic stagnation or retrogression to one of absolute economic progress. A leading feature of this process, of course, would be more rapidly rising real wages or the resumption of rising real wages.

A policy of abolishing taxes on profit and interest, or at least substantial movement in the direction of such a policy, is clearly urgently called for in the present-day United States, which is on the verge of becoming a stagnant or even retrogressing economic system. Yet it is greatly to be feared that the growing ignorance and envy of the present generation of Americans, and of their elected representatives, will prevent these necessary steps and instead carry the American people into growing poverty, and the United States ultimately into the backwaters of history.

The ignorance and envy of today's Americans are, of course, themselves to an important extent the product of the overthrow of the gold standard. The overthrow of the

gold standard served to break the connection between the rate of profit and the rate of economic progress, and to lead people to regard the high profits created by taxation and inflation as though they signified the rapid enrichment of business firms and their owners at the very time that the general public came to grow rich less rapidly or not at all. Thus the implication of the preceding analysis is no less a reinstatement of the gold standard.

7. How Government Budget Deficits Raise the Rate of Profit

The invariable-money/net-consumption analysis illustrated in Figures 16–2 and 17–1 makes it possible to understand the effects of persistent government budget deficits on the rate of profit.

Insofar as they are not financed by the creation of new and additional money, budget deficits are financed by the sale of securities in exchange for funds that otherwise would have entered mainly into productive expenditure.⁴⁵ As a result, just as in the case of taxes falling on productive expenditure, the demand for capital goods is reduced, and the demand for labor by business firms, and thus the demand for consumers' goods by the employees of business firms, is reduced. These reductions in the demand for capital goods and in the demand for consumers' goods by the employees of business are, of course, accompanied by an equivalent increase in the demand for consumers' goods by the government or by those to whom the government gives money. Thus, once again, just as in the case of taxes falling on productive expenditure, aggregate business sales revenues in the economic system are unchanged.

But, just as in the case of such taxes, while aggregate sales revenues are unchanged, the reduction in productive expenditure works to bring about an equivalent reduction in aggregate business costs that are deducted from sales revenues in computing profits. Therefore, the result once again is that the aggregate amount of profit rises correspondingly. The average rate of profit is raised by virtue both of the rise in the aggregate amount of profit and the reduction in the aggregate amount of capital invested. The difference between the effect of budget deficits on the rate of profit, and of taxes that reduce productive expenditure, is that in the case of budget deficits the rise in the rate of profit is a rise in the net, aftertax rate of profit, not merely in the gross, pretax rate of profit. This is because in this case, there is no rise in tax costs in the economic system to offset the fall in ordinary business costs that results from the fall in productive expenditure.

Of course, just as in the case of a fall in productive expenditure caused by taxation, the decline in productive

expenditure caused by budget deficits is inimical to economic progress, and, if carried far enough, must cause economic retrogression. In a word, the effect is once again that of moving from the progressive conditions described in Figure 17–1, in the direction of the stationary conditions described in Figure 16–2. In both cases—that is, taxes or budget deficits coming at the expense of productive expenditure—the rise in the amount and rate of profit signifies merely that in the context of an invariable money, an inverse relationship exists between aggregate profits and national income on the one side, and economic progress and prosperity on the other.⁴⁶

Obviously, all that was said in the preceding section about the urgent need to abolish or at least radically reduce the taxation of profit and interest incomes, and all other taxation falling on saving and productive expenditure, applies to government budget deficits.

The Need to Reduce Government Spending

The vital goal of increasing saving and capital formation through balancing the government's budget and cutting taxes that fall on saving and productive expenditure can be achieved very simply: namely, by *slashing government spending*. Such a policy would be consistent with reductions both in taxes falling on saving and productive expenditure and in taxes falling on consumption, and at the same time with a balanced government budget and, indeed, with government budget surpluses. Above all, it would be consistent with preserving and enlarging the freedom of the individual to spend his own income and wealth. The failure to reduce government spending, on the other hand, makes the achievement of greater saving and capital formation either altogether impossible or possible only at the price of sacrificing the freedom of the mass of wage and salary earners to dispose of their own incomes.

It should be clear that reducing taxes without reducing government spending cannot promote saving and capital formation, but must undermine them further, even if the funds no longer claimed by taxes are overwhelmingly saved. For in this case, the government must substitute a dollar of borrowing for a dollar of tax revenues. Each dollar borrowed is a dollar less of savings available for the rest of the economic system. Thus even if a dollar less of taxes results in as much as ninety cents of additional saving, there is a significant net reduction in the supply of savings available for the rest of the economic system. In this instance, while ninety cents of additional saving takes place as the result of tax reductions, a full dollar less of savings is available to business and private consumers as the result of the government's borrowing, and thus there is a net reduction of ten cents of savings available for every dollar of such tax cuts based on

increases in the government's deficit.

Tax cuts to promote saving and capital formation which are financed by deficit increases are thus simply contrary to purpose. The fact that they are contrary to purpose remains if, instead of being financed by borrowing, the resulting deficits are financed by the more rapid creation of money. In this case, all of the destructive effects inflation has on capital formation come into play, which effects I will show in Chapter 19.⁴⁷

By the same token, balancing the budget by means of raising taxes is destructive of saving and capital formation to the degree that the additional taxes fall on saving and productive expenditure. Ironically, it is precisely taxes that fall heavily on saving and productive expenditure that today's advocates of balancing the budget through tax increases favor. The taxes they wish to increase are precisely those which land on corporations and the so-called rich. The only way that these advocates of balanced budgets through tax increases could proceed consistently with the goal of capital formation would be by increasing the taxes of the very people they claim to favor, namely, the poor and the mass of wage and salary earners, who save relatively little. Indeed, the only way that greater saving and capital formation is possible in the absence of decreases in government spending, is by means not only of increasing such taxes to the point of balancing the budget, but also increasing them still further, to compensate for decreases in the kind of taxes that land more heavily on saving and productive expenditure. In essence, if one advocates greater saving and capital formation and yet refuses to support reductions in government spending, one is logically obliged to advocate increasing the taxes of wage and salary earners and of the "poor" in order both to balance the budget and to compensate for reductions in taxes on profits and interest and on the "rich."

But there is absolutely no reason to advocate such a downright fascistic policy.⁴⁸ Instead of sacrificing anyone to anyone, the simple, obvious solution is sharply to reduce the sacrificing that is already going on—namely, sharply to reduce and ultimately altogether eliminate pressure-group plundering and the government spending that finances it at the sacrifice of everyone.⁴⁹

The preceding analysis makes clear that an essential flaw of so-called supply-side economics—the policy of the Reagan administration—was its failure to face up to the need to reduce government spending. While the administration's program of tax reductions—in particular the reduction of the maximum rate of personal income tax on profit and interest income from 70 percent to 28 percent—was courageous and praiseworthy in the extreme, most of the potential benefit of the tax cuts was

lost through the corresponding enlargement of federal budget deficits. Regrettably, the administration and its supporters lacked the further courage required to abolish government spending programs to make those tax cuts possible without deficits.

The Government's Responsibility for the Emphasis of Today's Businessmen on Short-Term Results

Among the virtually endless criticisms of business is one of relatively recent origin, namely, that American businessmen are unduly concerned with short-run results, in contrast to the businessmen of such countries as Japan, who, it is claimed, attach much greater importance to long-run results.

There is an important measure of truth in this accusation. American businessmen of the present generation are much more concerned with short-term results than the businessmen of such countries as Japan and, indeed, than American businessmen of previous generations. But the reason for this situation is not, as is apparently believed, some intellectual or moral deficiency on the part of contemporary American businessmen. Totally apart from any such deficiency, which the climate of massive government interference and all of its accompanying subsidies, regulations, and associated influence peddling might well in fact foster, there is a profoundly important, objective difference between the economy of the present-day United States and that of contemporary Japan and of the United States of the past—a difference emanating from the same quarter. This is the difference in the magnitude of the government's assault on saving and productive expenditure and the consequent artificial elevation of the rate of profit and interest.

Because of anticapitalistic tax policies, compounded by major government budget deficits and decades of inflation, American businessmen have been placed in a situation in which they must evaluate all investment projects in the light of the need to earn a pretax rate of return of 12 to 15 percent or more, in order to be competitive. This means that any possible greater earnings that might be achieved in the long run stand at a correspondingly steep discount in comparison with earnings that can be obtained in the short run. In order, for example, for earnings which come in 5 years later to outweigh lesser earnings in the present, those earnings must be greater in a magnitude of 12- to 15-or-more-percent *compounded* over that 5 year period of delay—i.e., they must be greater by 76 to 101 percent or more ($1.12^5 = 1.76$, and $1.15^5 = 2.01$). In contrast, in contemporary Japan and in the United States of the past, businessmen are or were in a position to evaluate investment projects in the light of the need to earn perhaps merely a 5 or 6 percent rate of return or less. The significance of this is

exemplified by the fact that in these conditions, in order for greater earnings 5 years later to outweigh earnings in the current year, they need only be greater by 28 to 34 percent ($1.05^5 = 1.28$ and $1.06^5 = 1.34$). It is certainly much easier to be concerned with the long run under the latter state of affairs than under the former.

The responsibility for today's inordinate rate of profit and interest in the United States is squarely that of the U.S. government. At a deeper level, it is the responsibility of the pressure groups and the demagogues who are responsible for the government's pursuit of anti-capitalistic policies. Above all, at a deeper level still, it is the responsibility of the last several generations of intellectuals who, corrupted by the philosophy of irrationalism, altruism, and collectivism, have polluted the intellectual environment of the country to the point where there is little or no serious opposition to the activities of the pressure groups and the demagogues. Responsibility does *not* lie at the end of the line, in the hands of businessmen, who did not create the political-cultural environment in which they now must operate and who do not deserve this further vituperation from the intellectuals at what is in fact a consequence of their—the intellectuals—own, utterly destructive philosophy. It is perfectly consistent, however, that those who destroy, whether through ignorance or viciousness, should blame innocent victims for the consequences of their actions.

8. Profits, the Balance of Trade, and the Need for Laissez Faire in the United States

The previous section has shown that government budget deficits financed by the diversion of savings from productive expenditure to the government's consumption operate to reduce aggregate business costs to an equivalent extent—while leaving aggregate business sales revenues unchanged—and thus to raise the amount of profit in the economic system to an equivalent extent. So long as the outside world does not view the country concerned as firmly on the road to ruin, the resulting rise in its rate of profit acts as an attraction to foreign investment. This foreign investment alleviates the destructive effect of the budget deficits on domestic capital formation. At the same time, the excess of imports over exports that constitutes the foreign investment, operates to scale back the rise in the amount and rate of profit caused by the budget deficits and to spread that rise over the economic system of the countries that export on net balance to the country with the budget deficits.⁵⁰

These results can be made plain by mentally placing Figures 16–2 and 17–1 side by side. Figure 16–2, which should be imagined to be on the right, can be taken as representing the economy of the present-day United

States—with its placement on the right indicating the relative location of the United States on a map of the Pacific rim. Figure 17–1, on the left, can be taken as representing the economy of present-day Japan, and the relative location of that country on a map of the same region. The economy of the United States is characterized by Figure 16–2 because in the United States an annual budget deficit of 100 monetary units is responsible for a reduction of productive expenditure and costs by 100 monetary units in comparison with what they would otherwise have been, while sales revenues remain 1,000 monetary units. Thus, the budget deficit is responsible for productive expenditure and costs being only 800 in the United States, while they are 900 in Japan, and thus for a correspondingly higher amount and rate of profit in the United States than in Japan. At the same time, the budget deficits are responsible for the relative demand for and production of capital goods being less in the United States than in Japan, and thus for the economy of the United States stagnating while that of Japan rapidly progresses. (In reality, of course, other major factors are also at work causing economic stagnation in the United States and economic progress in Japan, but we ignore them for the sake of simplicity.)

Now imagine that in a given year some part of the output of the Japanese economy of Figure 17–1 is loaded onto ships and sent over to the U.S. economy of Figure 16–2. For example, one can imagine that in *Year 3*, say, 5 percent of the output of the Japanese economy is exported to the United States. (For the sake of simplicity, one can assume that there are no imports into Japan from the United States.)

The effect of this movement of goods is that the supply of goods in Japan in *Year 3* is reduced from $1.44K + .96C$ to $1.368K + .912C$, while the supply in the United States is equivalently increased, from $1K + 1C$ to $1.072K + 1.048C$. (These figures reflect the fact that 5 percent of $1.44K$ is $.072K$, while 5 percent of $.96C$ is $.048C$.) What is significant for the rate of profit is that while aggregate sales revenues in both countries remain at 1,000 monetary units each, with each monetary unit in Japan representing so many yen, and each monetary unit in the United States representing so many dollars, *the aggregate cost value of the goods remaining for sale in Japan is reduced by 5 percent*, while the aggregate cost value of the goods available for sale in the United States is equivalently increased.

Instead of there being $1.44K$ of capital goods at a cost value of 540, and $.96C$ of consumers' goods at a cost value of 360, for sale inside Japan for 1,000 of sales revenues, there are now only $1.368K$ of capital goods at a cost value of 513, and $.912C$ of consumers' goods at cost value of 342. (These cost values result from the fact

that 95 percent of 540 is 513, and 95 percent of 360 is 342.) Thus, in Japan, aggregate costs are reduced by the cost value of the goods exported, namely, by 27 plus 18, and aggregate profits, therefore, are increased equivalently, viz., from 100 to 145.

On the simplifying assumption that the dollar and the yen are freely convertible into one another at the exchange rate of 1 monetary unit for 1 monetary unit, it would follow that aggregate profits in the United States would be reduced from 200 to 155 in *Year 3*, owing to the sale of $1.072K$ of capital goods with a cost value of 427, and $1.048C$ of consumers' goods with a cost value of 418—that is, reduced by exactly the same amount as aggregate profits in Japan are increased. The principle would be present that the cost value of the goods exported/imported represented an equivalent rise in the aggregate profits of the exporting country and an equivalent fall in the aggregate profits of the importing country. This would be because in the one case—that of the exporting country—the cost value of the goods in question would be subtracted from the costs deducted from the same sales revenues, while in the other—that of the importing country—it would be added to the costs deducted from the same sales revenues.

In reality, foreign investment will not cause an immediate addition to profits in the exporting country, and an immediate reduction in profits in the importing country, equivalent to the cost value of the goods exported/imported. Rather it will cause less net investment in the exporting country and more net investment in the importing country. However, it is still the case that foreign investment does serve to make the costs deducted from sales revenues in the importing country greater, and those in the exporting country less, if not all at once, then over time, and thus the effect is still a rise in the amount and rate of profit in the exporting country and a fall in the amount and rate of profit in the importing country. Sooner or later, the repeated export of goods means a corresponding reduction in aggregate costs and rise in profits in the exporting country, while the repeated import of goods means a corresponding rise in the aggregate costs and fall in the aggregate profits of the importing country.

It should be obvious that the fact that both countries export as well as import does not change anything of significance. The results I have described hinge on *net exports/imports*.

Thus, the unmistakable conclusion to be drawn is that the American trade imbalance with Japan serves to deflect part of the destructive consequences of American budget deficits to Japan. In effect, it helps to replace some of the productive expenditure lost in this country as the result of government budget deficits, with the benefit of part of Japan's productive expenditure. In the process, it

diminishes the increase in the rate of profit in the United States that would otherwise result from the American government's budget deficits and transmits part of the elevated rate of profit of this country to Japan—and, of course, to all other countries that on net balance export to the United States. Thus, it serves to spread over the economic system of all trading nations the fall in productive expenditure and rise in the amount and rate of profit caused by government budget deficits in the United States.

The increase in the pretax rate of profit in the United States (or any other country) caused by the *taxation* of profits and interest, also serves to attract foreign investment and thus to cause an “unfavorable” balance of trade. This is the case to the extent that foreign suppliers are able to translate the higher pretax rate of profit into a higher aftertax rate of profit. This can occur by such means as foreign investors concealing part of their profits through overstating the cost of supplies they bring in from abroad.

The preceding discussion in this section did not go into the influence of differences in the rate of capital formation on the balance of trade. But it should be recalled from previous chapters that a rate of capital accumulation and economic progress that is below the world average implies that the economy of a country will constitute a declining proportion of the world's economy as time goes on, while, of course, the reverse is true of an economy with a rate of capital accumulation and economic progress that is above the world average. Of two such opposite economies, the latter will come to possess a growing proportion of the world's money supply while the former will come to possess a declining proportion of the world's money supply.⁵¹ This process too entails a so-called favorable balance of trade in the one, and a so-called unfavorable balance of trade in the other, insofar as both countries use the same money and movements in the supply of money between them take place in conjunction with the purchase and sale of commodities.⁵²

If one recognizes that the fundamental cause of America's trade imbalance with Japan is the higher rate of profit prevailing in the United States, which the trade imbalance operates to diminish, and the closely related slower rate of capital formation and economic progress in the United States, which the trade imbalance also helps to alleviate, then it follows that what will reduce or even eliminate the trade imbalance is a fall in the rate of profit in the United States, which would be accompanied by a higher rate of domestic capital formation.

If, in addition, one recalls the discussions of the two

immediately preceding sections of this chapter, then it becomes clear that what would accomplish a fall in the rate of profit in the United States and a higher rate of capital formation would be precisely the balancing of the U.S. government's budget and the radical reduction of taxes that fall on saving and capital formation. Better still, it would be the achievement of budget surpluses, accompanied by the total abolition of such taxes, above all, the corporate income tax, the progressive personal income tax, the inheritance tax, and the capital gains tax. The social security system and its diversion of hundreds of billions of dollars of savings into government consumption would also have to be phased out in favor of private saving supporting actual investment.⁵³ What all this requires, of course, is the abolition of the welfare state and the radical reduction of government spending in the United States.

Unless and until such measures are adopted, the United States as a whole will be in a position analogous to that of an individual capitalist who consumes at a rate above the net-consumption rate and whose relative wealth and income steadily declines in favor of others who consume at a rate below the net-consumption rate.⁵⁴ In order for the United States to retain its international position and not ultimately be relegated to the ranks of second- and third-rate nations, it is vital that its net-consumption rate fall to a point at least approximating that of Japan and the other rapidly progressing countries of East Asia. (As used in the present context, the net-consumption rate is to be understood as incorporating all elements that serve to elevate business sales revenues above productive expenditure. This includes all government consumption that is financed by means of funds obtained at the expense of productive expenditure, whether through taxes or through budget deficits. Such consumption takes place at the expense of a diminution of productive expenditure and at the same time maintains business sales revenues, thereby enlarging the magnitude of difference.) Only to the extent that the relative efficiency of the United States in using existing capital goods was greater than that of Japan and the other rapidly progressing economies of East Asia, could it afford to have a higher such net-consumption rate than they. Today, however, the United States probably substantially lags behind Japan and the others on this score too.

But the solution for both aspects of the problem is essentially the same: It is the radical reduction of government intervention in the economic system.⁵⁵ It is the coming home of the United States to full-bodied capitalism. It is the establishment of *laissez-faire* capitalism.⁵⁶ If this course is not pursued, then not only will the United States decline relatively, but it may also decline absolutely. The factors working to choke off economic prog-

ress by no means automatically stop at the point of stagnation. They easily go further and result in economic retrogression.

As indicated, the only alternative to laissez-faire capitalism that might be compatible with economic progress for a time is the utterly vicious one of a fascistic-style tax system that would place all or almost all of the enormous tax burden created by the welfare state on the consumption of the ordinary citizens, thereby lifting the burden that now falls on saving and capital accumulation.⁵⁷ This burden, of course, would have to be the greater, the more government intervention reduces the efficiency of the economic system in using existing capital goods. For this requires the existence of a greater relative production of capital goods and higher degree of capital intensiveness in order to achieve any given rate of economic progress. Government intervention for the purpose of actually achieving capital accumulation—notably, taxation for that purpose—would mean collecting taxes from the ordinary citizens as a source of capital, which capital would itself be used inefficiently and thus require still more such taxation. Capital accumulation under such conditions would have important features in common with attempted capital accumulation under communism.⁵⁸ It is an absurd and vicious method of capital accumulation.

At the very best, the enormous burden of taxation that must fall on the average person under the welfare state, in order for it to have capital accumulation and economic progress, means giving to people the very dubious and largely fictional benefits of the welfare state at the expense of much greater benefits they could have had without the welfare state and with the freedom to spend their own incomes as they wished. As shown throughout this book, people can have incomparably more and better education, medical care, and retirement security without the welfare state than with it, and in a measure that grows progressively greater the longer the period of time in which economic freedom exists rather than a welfare state.

Furthermore, such capital accumulation and economic progress as might be enjoyed under a welfare state are possible only if the welfare state remains stable, in the sense of not continually claiming a greater proportion of people's incomes, and only if no new government intervention adds further disabilities to the efficiency of production. But if the principle of economic freedom is abandoned and that of government intervention and the welfare state put in its place, it is impossible to assume that such stability would exist. More than likely, growing government intervention and a growing welfare state would deprive the masses of people of most or all of the benefit of the capital accumulation that took place. At the

same time, a growing disparity between their relatively stagnant conditions and the improving conditions of a small upper class of businessmen and capitalists and individuals prominent in such fields as the performing arts and professional sports, would fuel growing envy, and thus ultimately lead to the imposition or reimposition of a system of taxation and government finance that was incompatible with economic progress, period. Thus, laissez-faire capitalism—acceptance of the *principle* of laissez-faire capitalism—is essential to economic progress in the long run. It is the only system in which economic progress is possible without the exploitation of the so-called common man.

9. Implications for the Theory of Saving

Previous discussion in Chapter 16 has shown that in the conditions of an invariable money, net investment tends to disappear, leaving net consumption as the sole determinant of the amount and rate of profit.⁵⁹ A corollary of that discussion is that under an invariable money, *saving out of money income likewise tends to disappear.*

Net Saving and Increases in the Quantity of Money

Under an invariable money, the constancy of the quantity of money and volume of spending implies a constancy of aggregate money income. As we have already seen, it follows that under these conditions, saving out of income not only adds to the amount of accumulated savings and capital, but also signifies a rise in the *ratio* of accumulated savings and capital to income.⁶⁰ Yet as savings and capital accumulate relative to income, the need and desire of people to increase their savings and capital still further relative to their income diminishes, while their desire to consume their income increases. This is because the future is becoming progressively better and better provided for relative to the present by virtue of such saving and capital accumulation. As the desired ratio of provision for the future relative to the present is approached, the growth in the magnitude of accumulated savings and capital relative to income operates to increase the proportion of income that is consumed.⁶¹ This means that at some point under an invariable money, having achieved a sufficient ratio of accumulated savings and capital to income, and thereby having made sufficient provision for the future relative to the present, people stop adding to their savings and capital and consume their full nominal income.

Thus, in an economic system with an invariable money, an equilibrium is ultimately reached, in which saving out of money income and net investment in terms of money both disappear. It is an equilibrium in which the economic system ceases to grow more capital intensive

in the relative-value sense—i.e., in the sense of the ratio of accumulated savings and capital to income—and in which all money income is consumed.⁶²

Of course, in such an economic system, many individuals go on saving. For example, young people starting out in life must accumulate savings. But their saving is balanced by the dissaving of others, such as old people living in retirement, or people out of work because of illness or accident. In the system as a whole, there is no net saving in terms of money. Capital accumulation and economic progress in such circumstances take place exclusively in the form of falling prices.

The implication of the fact that saving out of money income tends to disappear in the conditions of an invariable money, is that *the existence of saving out of money income, as a permanent phenomenon, is the result of the continual increase in the quantity of money*. Indeed, the increase in the quantity of money operates continually to raise money incomes and thus to make necessary a continual increase in the absolute magnitude of accumulated savings and capital if any given ratio of accumulated savings and capital to money income in the economic system is to be maintained. Saving out of money income is necessary to provide the required increase in the magnitude of accumulated savings and capital in these circumstances.

For example, if people desire on average to maintain some given ratio of accumulated savings to current income, such as 3:1 or 4:1, and the increase in the quantity of money makes current nominal incomes rise by 2 or 3 percent per year, then it is necessary for total accumulated savings also to increase by 2 or 3 percent a year, or whatever the figure might be, in order to maintain the same ratio of accumulated savings to current income. This in turn implies a definite ratio of nominal net saving to current income. In the present examples, saving as a percentage of nominal net income must range from 6 percent to 12 percent, as the condition of accumulated savings continuing to bear the same ratio to nominal net income. This is because if a magnitude that is 3 times current income is to grow by 2 percent, the amount of its increase is 6 percent of current income. By the same token, if a magnitude that is 4 times current income is to grow by 3 percent, the amount of its increase is 12 percent of current income.

Thus saving as a percentage of current income appears as the product of the rate of increase in the quantity of money—and thus in nominal incomes—times the ratio of accumulated savings to current income that people wish to maintain on average. If there were no increase in the quantity of money and thus no increase in nominal net incomes, there would be no need for an increase in accumulated savings once the desired ratio of accumu-

lated savings to current income was achieved. Given an increase in the quantity of money and nominal net incomes, the need for additional accumulated nominal savings is the greater, the higher is the ratio of accumulated savings relative to current income that people wish to maintain.⁶³

Failing the increase in accumulated savings in a context in which an increase in the quantity of money and volume of spending continually raise money incomes, the effect would be a progressive fall in the degree of capital intensiveness in the economic system. For example, starting with an aggregate money income of 500, and 1,500 of accumulated capital, and thus a capital-net-output ratio of 3:1, a 2 percent annual increase in money income and no additions to accumulated savings would imply that in 35 years, when money income had doubled, the capital-net-output ratio would be halved. The capital-net-output ratio can be maintained at 3:1, only if over the course of this period of time there is saving out of income sufficient to increase accumulated capital to 3,000. Thus, in the context of an increasing quantity of money and rising volume of spending, continual net saving is necessary not to increase, but to maintain the degree of capital intensiveness.

Why the Actual Significance of Saving Lies at the Gross Level

The realization that saving out of money income tends to disappear in an economic system with an invariable money makes it possible to understand much more fully than would otherwise be the case precisely what role saving plays in relation to capital formation—viz., to the increase or decrease in the supply of capital goods. The disappearance of saving out of money income in an economy with an invariable money does *not* mean the disappearance of capital accumulation. The supply of capital goods can go on increasing. In such circumstances the increase in the supply of capital goods results in falling prices of capital goods, just as the increase in the supply of consumers' goods results in falling prices of consumers' goods. Each year, in these circumstances, the depreciation quotas recovered from previous investments are able to buy a larger supply of capital goods than the year before. Each year, the funds recovered in the sale of inventories make possible more than the mere replacement of those inventories. In other words, the same productive expenditure for capital goods buys a growing supply of capital goods at falling prices of capital goods. This, of course, is exactly what happens in Figure 17-1, which shows the demand for capital goods constant at 600 monetary units in every year from Year 2 on, while capital accumulation and economic progress continue at a rapid rate.

In such an economic system, the real connection between saving and capital formation becomes clear. The relationship is not one between saving out of money income and capital formation—it is not between *net* saving and capital formation. Rather it is between *gross* saving—mainly saving out of business sales revenues—and capital formation. (Gross saving also includes saving out of net income, when such saving exists. However, saving out of sales revenues and gross saving become synonymous in an economy with an invariable money, because of the disappearance of saving out of net income.)

As demonstrated repeatedly in this book, saving out of business sales revenues determines the demand for capital goods relative to the demand for consumers' goods. It thus determines the relative production of capital goods and in this way the rate of capital accumulation. This vital aspect of saving, namely, determining the relative production of capital goods, is what is clearly revealed under the conditions of an invariable money. As far as saving goes, this aspect is what is decisive in determining the rate of capital accumulation. And while saving out of net income can certainly enter into determining the relative production of capital goods, saving out of sales revenues is capable of discharging that function strictly by itself, when the conditions of an invariable money make it necessary—that is, it does so without the existence of net saving in terms of money income.

Furthermore, as I have repeatedly shown, saving out of sales revenues is also the essential determinant of the demand for labor. The greater is saving out of sales revenues relative to the sales revenues, the higher tends to be both the demand for capital goods and the demand for labor, relative to the demand for consumers' goods, and thus the higher and more rapidly rising the level of real wages. Saving out of sales revenues, in other words, is the essential determinant of what I have characterized as the economic degree of capitalism.⁶⁴ Again, saving out of net income can make a contribution, but the essential aspect of the role of saving is independent of the phenomenon of net saving, which is essentially to say that it is independent of the increase in the quantity of money.

A closely related aspect of the relationship between saving and capital formation that stands clearly revealed in the conditions of an invariable money, is precisely that between the *ratio* of accumulated savings and capital to such magnitudes as consumption and income, on the one side, and capital formation, on the other. As previously explained, the higher are such ratios, the more capital intensive is the economic system and the greater its ability to implement technological advances, which tech-

nological advances result in an increase in the supply not only of consumers' goods but also of capital goods.⁶⁵ Insofar as net saving signifies a rise in these ratios, it again signifies an acceleration in the rate of capital accumulation and economic progress—precisely because of its implication of a greater ability to implement technological advances.

Thus, the true significance of saving that is revealed in the conditions of an invariable money is that gross saving determines the relative production of capital goods along with the demand for labor relative to the demand for consumers' goods, and in these ways the height and direction of real wages. And, as an accumulated amount relative to current income, savings determine the degree of capital intensiveness of the economic system and thereby the ability to adopt technological advances and achieve capital accumulation and economic progress. The role of net saving, which in the long run reflects nothing more than the continual increase in the quantity of money, is entirely subsidiary.

It should be realized that the appearance of a direct, one-to-one relationship between net saving and capital accumulation, which is created by the increase in the quantity of money, serves both to conceal the role of saving in capital accumulation in one respect, and grossly to exaggerate it in another respect. On the one hand, it conceals the fact that in determining the relative demand for and production of capital goods, gross saving—when accompanied by technological progress—operates as force to acceleration in the accumulation of capital goods.⁶⁶ On the other hand, in creating the appearance that for every accumulation of capital, corresponding net saving must occur, it supports the belief that saving by itself is the source of capital accumulation. In this way, it serves to reinforce all the errors stemming from the fallacy that the production of consumers' goods constitutes production in its entirety and that the causes of capital accumulation have no essential connection with the causes that increase production in general, such as technological progress and economic freedom.⁶⁷

Net Saving and the Rate of Profit

In view of the widespread influence of the doctrine that saving (net saving) reduces the rate of profit, it is important to integrate two of the major propositions that have now been established in this chapter or the last one. Namely, that the existence of net saving as a permanent phenomenon is the result of the increase in the quantity of money and volume of spending, and that that same increase in the quantity of money and volume of spending adds a corresponding positive component to the rate of profit. It follows from these propositions that the net saving which takes place as a regular, continuing phe-

nomenon in the economic system is the accompaniment of a rate of profit which is not only not reduced by virtue of its existence, but in fact is *elevated* by virtue of the same cause that underlies its existence. Thus, insofar as net saving goes on for the most part, it is accompanied by a rate of profit that is higher, not lower, than would exist in its absence. Indeed, precisely the elevated rate of profit is the source of most of the net saving.

10. More on Saving and “Hoarding”: “Hoarding” as a Long-Run Cause of a Rise in the Rate of Profit

The fear of saving is perhaps even more widespread than the fear of production. I have already refuted one leading root of this fear, namely, the confusion of an increase in saving with an increase in the demand for money for cash holding.⁶⁸ Here it is necessary to add to that critique the observation that to the extent that people do desire to make provision for the future in the form of cash holding rather than in the form of business investment, the long-run effect, contrary to popular belief, is not to reduce, but to increase the rate of profit.

This is because insofar as net consumption takes place in proportion to accumulated savings in the form of cash holdings, a rise in the ratio of cash holdings in the economic system to capital in forms other than cash holdings means a rise in the ratio of net consumption, hence profit, to capital in forms other than cash. For example, if people wished to hold fully half of their accumulated savings in the form of cash and only half in the form of capital invested in assets other than cash, a net-consumption rate of 2 percent would generate an amount of profit equal to 4 percent of the capital invested in assets other than cash.⁶⁹ In the most extreme case imaginable, in which *all* provision for the future took place in the form of cash holding, the rate of profit would be infinite, for there would be a demand for consumers' goods, hence, the existence of sales revenues, but neither productive expenditure, costs of production, nor capital. The effect on the rate of profit would thus be the same as if people made no provision for the future.

“Cash hoarding” operates to reduce the rate of profit only in the short-run, insofar as it represents an increase in the demand for money for holding above its previous level and thereby brings about a decrease in the volume of spending and sales revenues. Here the result is to reduce net investment and, indeed, even to turn it negative. However, once the demand for money for holding stops increasing and stabilizes at the higher level, and the economic system becomes adjusted to the accompanying lower level of spending—viz., once costs deducted from sales revenues fall to equality with the lower level of productive expenditure—then the effect of the rise in the

ratio of net consumption to capital other than cash is felt and the rate of profit rises. In other words, the negative effect of cash hoarding on the rate of profit is purely transitory. The long-run effect is to increase the rate of profit.

Implications for the Critique of Keynesianism

That cash hoarding does serve in the long-run to raise the rate of profit provides an answer to the pretended fear of the Keynesians that in a free economy the rate of profit will be too low to make investment worthwhile and will thus lead to a limitless rise in “liquidity preference”—viz., cash hoarding.⁷⁰ The answer is that if the rate of profit ever were too low to make investment worthwhile and thus did result in cash hoarding, the effect of such cash hoarding, as we have just seen, would be to restore the rate of profit to a point high enough to make investment worthwhile.

The point I have just made in criticism of the Keynesians bears a mild resemblance to the so-called Pigou effect propounded by the neo-Keynesians, a resemblance which, frankly, embarrasses me, inasmuch as I consider the “Pigou effect” to be extremely weak as a criticism of Keynes.⁷¹ The similarity is simply that both my criticism and the Pigou effect recognize a connection between consumption and accumulated savings in the form of cash holdings and that the existence of this connection has negative implications for essential doctrines of Keynes. The difference is that while the Pigou effect claims merely that because of this connection, consumption expenditure will not fall in full proportion to a fall in wages and prices and thus that at some point a fall in wages and prices is capable of leading to full employment, my criticism here is that every increase in the relative significance of cash holdings operates directly to raise the rate of profit and thus to eliminate the central stumbling block to full employment claimed by the Keynesians, namely, the allegedly too-low rate of profit. However, as I show in Chapter 18, there are other forces operating far more directly and powerfully to raise the rate of profit when wage rates and prices fall, so that it is not at all necessary that the influence of greater relative cash holdings ever come into play. And in fact it would not, since recovery from a depression and the restoration of the rate of profit that is part of that recovery are accompanied by a reduced demand for money for holding, not an increased demand.

Indeed, contrary to the Keynesians, the truth is that apart from some short-term, relatively inconsequential funds that might be held as cash rather than lent out, as the result of a lower rate of profit, the rate of profit in a free economy can never be too low to make investment worthwhile, even in the conditions of an invariable money.

This is because in a free economy, the average rate of profit and interest must always be significantly positive, for in such an economy there is no government intervention in money and banking, thus no inflation or credit expansion, and thus no financial contractions or depressions.⁷²

As we have seen, in the absence of inflation and credit expansion and thus of financial contraction and deflation, a positive rate of profit and interest is guaranteed by virtue of the operation of net consumption and net investment. Even if the saving of wage earners temporarily made net consumption negative, net investment and the consequent accumulation of capital and savings would take place to the point of sufficiently enlarging capital and accumulated savings relative to current income, to render net consumption positive once again.⁷³ The positive rate of profit that net consumption and net investment guarantee means that investment must be worthwhile.⁷⁴ In an economy with a commodity money, which is what any free-market economy would be, and in which, therefore, the rate of profit contains a significant monetary component, the impossibility of the rate of profit being too low to make investment worthwhile is doubly strong.

11. Critique of the Investment-Opportunity and Underconsumption/Oversaving Doctrines

Following the confusion of saving with cash hoarding, the second and third grounds for the fear of saving can be termed respectively the doctrine of lack of investment opportunity and the doctrine of underconsumption or, equivalently, oversaving. These two doctrines are similar in that both fear saving as bringing about the existence of capital or capital goods without profitable uses for them.

The investment-opportunity doctrine holds that the rate of profit and interest is determined by the supply of and demand for “capital,” which last it understands interchangeably as a sum of monetary value and a supply of physical capital goods. It views net saving as the source of all additional capital and, in the face of a given demand for capital, as driving down the rate of profit, just as a larger supply of any good, in the face of a given demand for it, drives down its price. Specifically, a growing supply of capital is supposed to encroach more and more on the allegedly limited opportunities that exist for the profitable investment of capital. These opportunities allegedly reflect the net physical productivity of capital and become progressively less rewarding as the supply of capital is increased, because of the operation of the law of diminishing returns.⁷⁵ The investment-opportunity doctrine regards technological progress as es-

sential for creating new and additional investment opportunities and thereby raising the demand for capital in the face of the increasing supply of capital provided by saving. It fears that in the absence of technological progress or sufficient technological progress, the supply of capital and capital goods will increasingly use up the limited profitable opportunities for investment and thereby drive the rate of profit toward zero. Only technological progress, it maintains, can prevent this from happening and keep up the rate of profit. Technological progress, it holds, is valuable because it creates a new and additional demand for capital to keep pace with the new and additional supply generated by saving, and thus operates to prevent the rate of profit from steadily falling.

The investment-opportunity doctrine obviously derives from the productivity theory of profit and interest, which I refuted in the last chapter.⁷⁶ It is utterly confused and mistaken in virtually every respect, not the least of which is its failure to see that the rate of profit is not determined by demand and supply but, above all, by the *difference* between the demand for products and the demand for factors of production—that is, by net consumption—specifically, by the rate borne by net consumption to the total of capital invested.⁷⁷

I have already substantially refuted the investment-opportunity doctrine in my critique of consumptionism, in Chapter 13.⁷⁸ Here it is only necessary more or less to summarize that critique and name a few additional points of criticism implied by the further knowledge provided in the intervening pages of this book.

As I have shown, the investment-opportunity doctrine’s fear of an accumulation of capital goods in the face of the absence of technological progress, or of insufficient technological progress, is absurd. Without technological progress, there can be no significant capital accumulation. Moreover, as I showed, the investment-opportunity doctrine is unaware that within the framework of any existing state of technology the need for capital goods always enormously surpasses the supply of capital goods actually available or that can be made available. The need for capital goods encompasses the need for all the capital goods required to make possible the production of the best-known models of all consumers’ goods, including the most expensive and luxurious—to the point of satiating the desire for those consumers’ goods. It encompasses the need for all the capital goods required directly or indirectly in the production of any consumers’ good—at any stage, however remote—to make possible its production by means of the most capital-intensive methods of production that are capable of achieving any reduction in cost or improvement in quality whatever. Until that point is reached—which it never will be—capital goods are scarce. The investment-opportunity

doctrine does not see that the real need for technological progress is to provide capital goods, not uses for capital goods—that is, to provide the goods that are physically to be invested, not opportunities for investment.

The doctrine is utterly confused in the role it assigns technological progress, namely, as a source of greater “demand for capital” and thus of a rise in the rate of profit, when in fact technological progress is the source of a greater *supply of capital goods* and thus of a fall in the prices of capital goods. Along with the fall in the prices of capital goods, as we know, technological progress is the source of a rise in the productivity of labor and thus of a fall in labor costs per unit. As a result of these facts, technological progress is responsible for a reduction in unit costs of production as well as being responsible for falling product prices.⁷⁹ As a further result, it is responsible for the falling prices of consumers’ goods that it causes not being the cause of a fall in the rate of profit or of “deflation,” which is the belief of the supporters of the investment-opportunity doctrine—in direct contradiction of their belief that technological progress is the cause of a higher rate of profit by virtue of its alleged contribution to the demand for capital.

As we have seen, technological progress simply has no connection with the average rate of profit in the economic system, apart from the contribution it makes to increasing the supply of commodity money. The rate of profit is governed entirely by the rate of net consumption and the rate of net investment, with the influence of the rate of increase in the quantity of money and volume of spending manifested almost entirely through the rate of net investment.

Ironically, to the extent that technological progress does contribute to raising the average rate of profit—through its effect on the supply of commodity money—it does so precisely in conjunction with its responsibility for the existence of net investment and net saving in terms of money. As already explained, both of these phenomena, insofar as they are permanent, are the result of the increase in the quantity of money and volume of spending. Thus, technological progress, which is supposed to be the source of a greater demand for capital that is allegedly necessary to solve the problem of an increasing supply of capital and capital goods provided by saving, is in fact the source not only of the additional supply of physical capital goods, but also—under a commodity-money system—of the additional savings and capital that are available in monetary terms. And, as we know, these additional savings and capital in monetary terms are accompanied by corresponding additions to the amount and rate of profit, rather than by any necessity of a fall in the rate of profit. The additions to the amount and rate of profit are part of exactly the same process—

namely, the effects produced by the increase in the quantity of money and volume of spending—that is responsible for the additional savings and capital in monetary terms. In this process, it is the additional net investment that is caused that provides the additional profitability, not any alleged increase in the “demand for capital” that technological progress is supposed to cause.

The reason the investment-opportunity doctrine is unaware of the profound, ineradicable scarcity of capital goods, is that it mistakenly believes, in essence, that the only use for additional capital goods is in the form of more and better machinery used to produce consumers’ goods. Thus it largely does not understand what can physically be done with an additional supply of capital goods if it becomes available. At the same time, as we know, it believes—in ignorance and contradiction of everything said above—that saving, unaided by technological progress, is potentially capable of providing practically unlimited supplies of additional capital goods. It is on the basis of these beliefs that it comes to the conclusion that a danger exists of technological progress not providing sufficient possibility of using additional capital goods at the very time that saving is generating a flood of capital goods, and thus that there is simply no good use to which the additional capital goods can be put. Given its confusion between increases in the supply of capital goods, which in fact reduce the prices of capital goods and thus help to reduce costs of production, and increases in the supply of “capital,” which allegedly reduce the rate of profit, the consequence of these beliefs is the doctrine of “secular stagnation.” This last, as we have seen, claims that in the absence of sufficient technological progress, saving causes depressions by virtue of bringing about too low a rate of profit to make investment worthwhile.⁸⁰

In addition to its ignorance of the vital role of technological progress as a source of capital accumulation, and of the virtually limitless need for additional capital goods within the context of the existing state of technology, the investment-opportunity doctrine, as we know, is totally unaware of the limitations of saving as a source of capital accumulation. It does not realize how limited is saving at all times, because of the operation of time preference. Nor, of course, does it see how limited would be the ability to accumulate capital goods merely on the strength of saving—that is, in the absence of technological progress—even if radically more saving took place relative to income than is ever likely to take place.

The reason for the investment-opportunity doctrine’s enormously exaggerated view of the power of saving, unaided by technological progress, to bring about capital accumulation, is the continuing existence of net saving in terms of money and thus the appearance of a more or

less one-to-one relationship between such nominal net saving and capital accumulation in physical terms. The investment-opportunity doctrine does not see that the continuing existence of nominal net saving, rather than reflecting any direct, one-to-one relationship between saving and capital accumulation, is actually the result of nothing more than the increase in the quantity of money. It does not see that nominal net saving takes place in connection with capital accumulation not as a fundamental cause, but merely as the result of the increase in the quantity of money and volume of spending. These go on as the by-product of the fact that technological progress and a sufficiently high relative demand for capital goods—the actual causes—bring about capital accumulation and increases in production, including the production of the good or goods serving as money. In this connection, the investment-opportunity doctrine does not realize that precisely technological progress is what allows a constant relative demand for capital goods and a constant proportion of gross saving to result in capital accumulation; and a rise in the relative demand for capital goods and the proportion of gross saving, to result in an acceleration of capital accumulation.⁸¹ It is unable to see that net saving in terms of money simply plays no fundamental permanent role in capital accumulation. Considered as a permanent phenomenon, it is, as I say, merely a by-product of the process of capital accumulation and rising production.⁸²

What the investment-opportunity doctrine does is to confuse the net saving that goes on in the world of an increasing quantity of money with the net saving that goes on in the world of an invariable money. It fails to realize that in the world of an increasing quantity of money, in the very nature of the case, virtually all of the net saving that exists is accompanied by a corresponding elevation of the rate of profit, and, indeed, takes place largely out of that elevated rate of profit. Instead, it proceeds—implicitly—as though the conditions of an economic system with an invariable money obtained, in which case every act of net saving would have to be the result of a fall in the rate of net consumption. If, indeed, those conditions did obtain, the rate of profit would have to fall with every repetition of net saving. But in those conditions, net saving in terms of money would come to an end, and thereafter capital accumulation would proceed without it. It would proceed with a given magnitude of accumulated savings and capital that stood in a sufficiently high, but not continually rising, ratio to consumption.

The investment-opportunity doctrine's errors on all of these scores are, of course, compounded by its acceptance of the prevailing confusions between the production and purchase of capital goods and the production and

purchase of consumers' goods—namely, the Platonic-Heraclitean view of entities that I have so extensively described and criticized.⁸³ This last, by obliterating the very existence of the production of capital goods as distinct entities that exist separately from consumers' goods—especially the production of materials, components, supplies, and all kinds of semimanufactures—underlies the investment-opportunity doctrine's belief that the only use of capital goods is in the form of machinery to produce consumers' goods. It leads to its failure to see both the use of capital goods in the production of further capital goods and the extent of the use of capital goods in the production both of capital goods and consumers' goods.

This brings me to the underconsumption/oversaving doctrine, which is, perhaps, even more crucially dependent on the confusions fostered by the Platonic-Heraclitean view of entities than is the investment-opportunity doctrine. The underconsumption/oversaving doctrine fears a lack of profitable uses for additional capital because it does not understand certain essential monetary aspects of the process of saving and capital formation. In effect, it believes that saving places business in the contradictory position of spending more to produce its products at the very time that its sales receipts are reduced by virtue of the fall in consumer spending that underlies the additional saving.

The fears of the underconsumption/oversaving doctrine can be found in the following passage from J. A. Hobson, a late nineteenth-, early twentieth-century writer who is quoted with approval on the subject by Keynes:

The object of production is to provide 'utilities and conveniences' for consumers, and the process is a continuous one from the first handling of the raw material to the moment when it is finally consumed as a utility or a convenience. The only use of Capital being to aid the production of these utilities and conveniences, the total used will necessarily vary with the total of utilities and conveniences daily or weekly consumed. Now saving, while it increases the existing aggregate of Capital, simultaneously reduces the quantity of utilities and conveniences consumed; any undue exercise of this habit must, therefore, cause an accumulation of Capital in excess of that which is required for use, and this excess will exist in the form of general over-production.⁸⁴

Actually, this passage can be interpreted as representing the fears of both the underconsumption/oversaving doctrine and the investment-opportunity doctrine. Insofar as it can be interpreted as a complaint about an alleged physical problem of how to employ the additional capital goods made possible by additional saving, it represents the fears of the investment-opportunity doctrine. Insofar as it can be interpreted as a complaint about a reduction of consumer spending in the face of an increase in the

spending for factors of production, it represents the fears of the underconsumption/oversaving doctrine.

In connection with the former, it is sufficient to observe here that Hobson is apparently unaware that a reduction in consumption spending and rise in accumulated savings serves to increase the physical volume of consumption in the future, by means of making business more capital intensive, and that the additional capital is useful in any or all of the ways I described in the discussion of the vertical dimension of the scarcity of capital.⁸⁵ He appears to believe that when people consume less and save more, they permanently reduce the physical quantity of goods they consume, while having accumulated the capital to produce a larger quantity of consumers' goods.

However, I believe that Hobson's real difficulty here is his inability to understand how a smaller volume of consumer spending can support a larger volume of invested capital in terms of monetary value and, above all, a larger volume of spending for capital goods. I believe that it is this which prevents him from seeing how the smaller volume of consumer spending can purchase the growing volume of physical output that results from the greater capital invested. This fear of how a smaller volume of consumer spending can support a larger volume of capital and capital spending is, of course, the essence of the underconsumption/oversaving doctrine, to the detailed critique of which I now turn.

The Basic Error of Underconsumptionism

Underconsumptionism fears saving because it is based on the belief that the aggregate demand for goods *as such* consists essentially just of the demand for consumers' goods. This belief, which I thoroughly refuted in Chapter 15, easily leads to the fear that saving places business in a contradictory position, in which it cannot escape from losses. For it then appears that if what is saved is to be invested, i.e., productively expended, that business is placed in the position of having to spend more for the means of producing its products at the very time that it receives less from the sale of its products. Underconsumptionism believes that consumers alone reimburse business for its outlays made in purchasing factors of production and thus that if consumption falls, the sales revenues of business fall equivalently. On this basis, a rise in the demand for capital goods made possible by an equal fall in the demand for consumers' goods must, according to underconsumptionism, place business in the position of spending a larger sum for the means of producing its products at the very time that it receives a smaller sum in the sale of its products. Indeed, once the expenditure by business for factors of production comes to equal the receipts obtained from the sale of consumers'

goods, then, supposedly, all profit is wiped out. And once the expenditure for factors of production comes actually to exceed the receipts obtained from the sale of consumers' goods, then, supposedly, losses must result. Only a sufficient demand for consumers' goods, and corresponding lack of saving, underconsumptionism holds, can ensure the profitability of business.

To illustrate the underconsumptionist doctrine in quantitative terms, if the demand for consumers' goods is 500 monetary units and the demand for labor, 300 monetary units, as is the case in Figure 16–2, then, according to underconsumptionism, business can be profitable only if the demand for capital goods is less than 200 monetary units. If, for example, the demand for capital goods is 100 monetary units, then, according to underconsumptionism, business can be profitable in the amount of 100 monetary units. For in this case, it would have total costs in the amount of 400 monetary units (300 of cost on account of labor plus 100 of cost on account of capital goods), while its sales revenues were equal to the 500 monetary units of consumption expenditure.

Underconsumptionism regards the actual conditions of Figure 16–2, and, even more, those of Figure 17–1, as placing business in the position of having to incur an aggregate loss. For it believes that with only 500 monetary units of consumption expenditure to generate sales revenues, and a demand for factors of production of 800 monetary units generating costs of production, which is the situation in Figure 16–2, an aggregate loss of 300 must ensue. According to underconsumptionism, the case is even worse in the conditions of Figure 17–1, because there a consumption expenditure of only 400 monetary units is left to cover costs generated by 900 monetary units of productive expenditure (which last, of course, is the sum of the 300 monetary units of demand for labor plus the 600 monetary units of demand for capital goods).

Putting aside the fact that Figure 16–2 is already supposed to imply major losses, the transition from the conditions of Figure 16–2 to those of Figure 17–1 provides exactly the kind of dreaded situation described by Hobson, namely, a diminution in the demand for consumers' goods and at the very same time an increase in the expenditure for factors of production, which factors of production have no other ultimate purpose but "to provide 'utilities and conveniences' for consumers." By examining this transition, it is possible to understand exactly why it is that the "exercise of this habit [of saving]" does *not* "cause an accumulation of Capital in excess of that which is required for use"—that it does not in fact result in an aggregate loss. This benevolent outcome is already apparent inasmuch as Figure 17–1 unquestionably shows that the additional saving and productive expenditure are actually accompanied by an aggregate

profit of 100, despite the fact that productive expenditure rises to 900 while the demand for consumers' goods falls to 400.

The explanation is that *the demand for capital goods is a demand for goods*. It is fully as much a demand for goods as is the demand for consumers' goods. Thus business is in no way exclusively dependent on the demand for consumers' goods for its sales revenues, because the demand for capital goods is in every respect as good a source of sales revenues as is the demand for consumers' goods. When the demand for capital goods is taken into account in the respective cases of Figures 16–2 and 17–1, it turns out that sales revenues are not merely the respective 500 and 400 of demand for consumers' goods, but include as well the respective 500 and 600 of demand for capital goods. Sales revenues in both cases are 1,000. As a result, the productive expenditures of Figures 16–2 and 17–1, in the amounts of 800 and 900 respectively, are not deducted merely from the sales revenues constituted by the respective annual consumption expenditures of 500 and 400, but from sales revenues of 1,000.

It must be kept in mind that in each year in Figures 16–2 and 17–1 there is a demand for capital goods as well as consumers' goods. Thus, when the outlay for factors of production in each year shows up as a cost deducted from the sales revenues of the following year, it is deducted from sales revenues which are constituted not only by the demand for consumers' goods of the following year but no less by the demand for capital goods which is made in that following year. In the conditions of Figure 16–2, only *half* of the 800 outlay for factors of production in each year shows up as a cost of producing the consumers' goods of the following year, for the sales revenues of the following year are only 50 percent constituted by the consumption expenditure of 500. Fully the remaining half of the 800 of productive expenditure shows up as a cost of producing the capital goods of the following year, which also bring in sales revenues 500. The fact that in Figure 16–2 fully as much cost is deductible from receipts from the sale of capital goods as from receipts from the sale of consumers' goods has been shown from the very first, in the description of each year's output as "1K OF CAPITAL GOODS at a Cost Value of 400" and "1C OF CONSUMERS' GOODS at a Cost Value of 400." (Italics added.)

In the transition from the conditions of Figure 16–2 to those of Figure 17–1, first 60 percent of the initially prevailing 800 outlay for factors of production comes to be deducted from the 600 of receipts from the sale of capital goods. That is to say, the cost value of the capital goods of *Year 2* rises to 480 from the 400 cost value of the capital goods of *Year 1*. At the same time, only 40

percent of the initially prevailing 800 outlay for factors of production comes to be deducted from the 400 of receipts from the sale of consumers' goods—viz., the cost value of the consumers' goods of *Year 2* actually declines to 320 from the 400 of *Year 1*, corresponding to the fall in demand for consumers' goods from 500 to 400. From *Year 3* on, of course, the 100 increase in the demand for capital goods that commenced in *Year 2* shows up in the aggregate costs of production. At that point, 60 percent of this 100 addition to the demand for factors of production is deducted from the 600 of receipts from the sale of capital goods while only 40 percent of it is deducted from the 400 of receipts from the sale of consumers' goods. In other words, the cost of the capital goods produced comes to be 60 percent of the now prevailing 900 of productive expenditure, while the cost of the consumers' goods produced comes to be 40 percent of the now prevailing 900 of productive expenditure—viz., the respective aggregate costs of capital goods and consumers' goods come to be 540 and 360. All of this was shown in Figure 17–1.

The principle here is not only that the demand for capital goods is fully as much a demand for goods as is the demand for consumers' goods, but also that *the demand for factors of production is fully as much deductible as cost from receipts from the sale of capital goods as it is from receipts from the sale of consumers' goods*. Factors of production are used to produce capital goods no less than consumers' goods, and the expenditure for such factors of production is deductible as cost from the receipts from the sale of the capital goods, just as expenditure for factors of production to produce consumers' goods is deductible as cost from the receipts from the sale of the consumers' goods.

Further, to the degree that the demand for capital goods rises relative to the demand for consumers' goods, a correspondingly larger proportion of the factors of production comes to be employed in the production of capital goods relative to the production of consumers' goods, and thus *a correspondingly larger proportion of the demand for factors of production comes to be deductible as cost from receipts from the sale of capital goods rather than from receipts from the sale of consumers' goods*. And to the degree that a larger demand for capital goods represents a larger demand for factors of production in toto—that is, a larger demand for capital goods and producers' labor taken together—the addition to the demand for factors of production is allocated as additional cost of capital goods and additional cost of consumers' goods in proportion to the changed relative demands for capital goods and consumers' goods. What is present is both a shift in the disposition of a given amount of productive expenditure as between the pro-

duction of capital goods and the production of consumers' goods, and an increase in the overall total amount of productive expenditure. The larger total of productive expenditure shows up as cost of capital goods and consumers' goods respectively, in proportion to the changed relative demands for capital goods and consumers' goods.

Thus, as I have said, in Figure 17-1, when the demand for capital goods rises from 500 to 600 and the demand for factors of production in toto, from 800 to 900, while the demand for consumers' goods falls from 500 to 400, there is both a shift in the disposition of the demand for factors of production from a $50/50$ ratio in the production of capital goods and consumers' goods to a $60/40$ ratio, and then, in addition, a rise in the absolute demand for factors of production in the production both of capital goods and consumers' goods. The transitory result is that in anticipation of the change in relative demands, the demand for factors of production to produce capital goods rises from 400 to 480 (60 percent of 800), while the demand for factors of production to produce consumers' goods falls from 400 to 320 (40 percent of 800). The permanent result, once the 100 of additional demand for capital goods actually takes place and enlarges the demand for factors of production, is that the demand for factors of production to produce capital goods rises to 540 (60 percent of 900) and the demand for factors of production to produce consumers' goods rises to 360 (40 percent of 900), reflecting both a continuation of the changed relative allocation of the demand for factors of production and its absolute enlargement.

Understanding this twofold effect of a rise in the demand for capital goods and the overall demand for factors of production accompanying a fall in the demand for consumers' goods, makes it possible to carry the critique of underconsumptionism further, in the discussions that follow immediately below.

How the Demand for Capital Goods and Labor Can Radically and Permanently Exceed the Demand for Consumers' Goods

In order to place the alleged problem of underconsumption in the clearest possible light, and then show further why, in fact, there is no problem, let us consider a very extreme case.⁸⁶ Let us imagine that in the economic system as a whole, total spending for consumers' goods each year is 200 units of money. At the same time, let us imagine that total spending for capital goods in the economic system each year is the enormously greater sum of 800 units of money, and that the demand for labor is 100 units of money. Thus, we assume that the total demand for factors of production is 900, while the demand for consumers' goods is only 200. (The 200 of demand for consumers' goods should be understood as

constituted by 100 of consumption on the part of the wage earners employed by business and by 100 of net consumption on the part of businessmen and capitalists.) Given these assumptions, it appears to the underconsumptionists that business is placed in the position of buying its factors of production for 900 units of money each year while having to sell its products—the consumers' goods—for only 200 units of money each year. It thus appears that business is locked into the position of having to sell its products at an annual aggregate loss of 700 units of money, for it regularly buys for 900, and yet just as regularly sells for only 200.

It should already be obvious that in fact the sales revenues of business available to defray its outlay of 900 for the factors of production are not 200, but 1,000, consisting not only of the following year's consumption expenditure of 200 but, far more importantly in terms of size, the following year's 800 of demand for capital goods. In the conditions of this example, only 20 percent of the total aggregate demand for goods is a demand for consumers' goods, while 80 percent is a demand for capital goods. Thus, only 20 percent of the capital goods and labor of each year are employed in producing consumers' goods for the following year, while 80 percent are employed in producing capital goods for the following year. Accordingly, of the 900 monetary unit demand for factors of production only 180 (20 percent of 900) are charged against the sale of consumers' goods, while the remaining 720 (80 percent of 900), are charged against the sale of capital goods.

Indeed, if matters were as the underconsumptionists believe, and the 900 of demand for factors of production were all chargeable against the 200 of receipts from the sale of consumers' goods, the resulting 700 of loss in the consumers' goods industries would be accompanied by 800 of profit in the capital goods industries, because they would have sales receipts of 800 and *zero* costs of production since no productive expenditure would take place in their production. Such a situation is obviously impossible. Any higher rate of profit in the capital goods industries than in the consumers' goods industries would result in the withdrawal of capital and labor from the latter and their employment in the former. In the circumstances of our example, equalization of the rate of profit in the two sets of industries requires the employment of 80 percent of the factors of production in the production of capital goods and only 20 percent in the production of consumers' goods. The underconsumptionists simply fail to recognize that the expenditure for capital goods represents sales revenues to the sellers of capital goods. They see the expenditure for capital goods exclusively as showing up as a cost, and because they fail to recognize that receipts from the sale of capital goods are sales

receipts, they see all the cost corresponding to the expenditure for capital goods as a cost exclusively to the consumers' goods industries. They commit these fallacies because they believe that receipts from the sale of capital goods have no separate existence—that they are somehow counted in receipts from the sale of consumers' goods and that to acknowledge their separate existence would be to commit the alleged error of “double counting.”⁸⁷

Table 17–1 provides an economy-wide income statement in elaboration of this example. In the column headed “Economy as a Whole,” it shows total sales revenues and total costs in the economic system, and then, in the columns headed “Consumers' Goods” and “Capital Goods,” a breakdown of total sales revenues and total costs into the sales revenues and costs of the consumers' goods and capital goods industries respectively. In all three columns, total costs are broken down into cost specifically on account of capital goods and cost specifically on account of labor. (Costs in each case, of course, are the reflection of productive expenditures.) In addition, profits are shown, both for the economic system as a whole and separately for the production of consumers' goods and capital goods respectively.

Table 17–1 shows that of the 800 worth of capital goods annually purchased, only 160 are employed in the production of next year's 200 worth of consumers' goods, and 640 are employed in the production of next year's 800 worth of capital goods. (This is shown in the row labeled “On Account of Capital Goods,” under the heading “Cost.”) The table also shows that of the 100 worth of labor annually purchased, only 20 are employed in the production of next year's 200 worth consumers' goods, while 80 are employed in the production of next year's 800 worth capital goods. (This is shown in the row labeled “On Account of Labor,” under the heading “Cost.”)

Accordingly, in the production of consumers' goods, where sales revenues are 200 and total costs are 180 (160 + 20), profits are 20. In the production of capital goods, where sales revenues are 800 and total costs are 720 (640 + 80), profits are 80.

A second table, Table 17–2, goes on to describe not only how the outlay for capital goods and labor is allocated between the production of consumers' goods and capital goods in general, but also how it is allocated within the category of capital goods among the production of capital goods of various specific degrees of remove from the production of consumers' goods. The first column of the table represents a series of years, starting with *Year N* and extending on into the indefinite future, ultimately to *Year N+n*. Each year is assumed to be identical with the following year and with the preceding year, since the table depicts a continuing equilibrium under an invariable money. In the table, the column headed *s* represents aggregate sales revenues, while the columns headed *D_C* and *D_K* represent the respective demands for consumers' goods and capital goods, which, taken together, are equal to those sales revenues, and respectively constitute them in the form of receipts specifically from the sale of consumers' goods or specifically from the sale of capital goods. Thus far, the table does not add anything to what was already shown in Table 17–1.

Proceeding over to the right in the table, $D_C + D_K$ are shown to equal D_C plus a breakdown of D_K into a series of subcomponents: $D_{K1} + D_{K2} + \dots$. Implicitly, the last term here should be shown as D_{Kn} , but the table goes only as far as D_{K4} , for lack of room.

In the table, D_{K1} represents that part of the expenditure to buy capital goods in any year which is specifically for the purpose of producing the consumers' goods of the

KEY:

s = Sales revenues.

D_C = Demand for consumers' goods.

D_K = Demand for capital goods.

D_{K1} = Demand for capital goods to produce consumers' goods.

D_{K2} = Demand for capital goods to produce the capital goods to produce consumers' goods.

D_{K3} = Demand for capital goods to produce the capital goods described under D_{K2} .

D_{K4} = Demand for capital goods to produce the capital goods described under D_{K3} .

next year. This sum, as we already know, is 160, on the principle that the proportion of the total expenditure for capital goods which is for the purpose of producing consumers' goods is in proportion to the portion of total sales receipts which is obtained in the sale of consumers' goods. Receipts from the sale of consumers' goods of 200 represent 20 percent of the total sales receipts of 1,000 in every year, and thus 20 percent, or 160, of the 800 of expenditure to buy capital goods in any given year is assumed to be chargeable to the sale of consumers' goods in the next year.

By the same token, 20 percent of the 100 of total expenditure for labor, namely, 20, is also assumed to be chargeable to the sale of consumers' goods in the next year, as cost on account of labor. The expenditure for labor in each year is shown directly below the corresponding expenditure for capital goods. Thus, the 20 appears immediately below the 160. Both together represent the cost of producing the 200 worth of consumers' goods output available in the following year. In each year, a downward and leftward sloping arrow runs from the 160 and 20 of expenditure for factors of production to produce consumers' goods, to the 200 of sales pro-

ceeds brought in by those consumers' goods in the following year. This 160 worth of capital goods and 20 worth of labor can be described as representing the value of factors of production at one degree of remove from the production of consumers' goods. In the terminology of Menger and the Austrian school, they are goods and services of the second order.⁸⁸

In the table, D_{K2} represents that part of the outlay for capital goods in any year which is specifically for the purpose of producing those capital goods of the next year which will stand at one degree of remove from the production of consumers' goods, that is, those capital goods of the next year which will be used to produce consumers' goods for the year after next. Thus, D_{K2} is the portion of the outlay for capital goods in any given year that is devoted to the production of capital goods falling specifically under the heading of D_{K1} in the following year. D_{K2} and the demand for labor that accompanies it represent the demand for capital goods and labor at two degrees of remove from the production of consumers' goods.

By way of elaboration, the fact that in each year there is 160 of expenditure for capital goods that is specifically

for the purpose of producing the consumers' goods of the following year means that in each year there are 160 of *receipts* specifically from the sale of such capital goods. In each year, therefore, a specific portion of the total outlay for capital goods and labor must be viewed as chargeable against *this specific portion of next year's receipts*. In other words, some portion of the outlay for capital goods and labor in any given year is devoted specifically to the production of those capital goods of the next year which in the following year will be devoted to the production of consumers' goods. Just as D_{K1} is the specific portion of the outlay for capital goods in any given year that is chargeable to the D_C of the following year, so D_{K2} is the specific portion of the outlay for capital goods of any given year that is chargeable to the D_{K1} of the following year.

The value of D_{K2} is taken as 128 because the 160 of demand for capital goods to produce consumers' goods—viz., D_{K1} —is 16 percent of the 1,000 aggregate demand for all goods combined. It follows, on the same principle as previously applied, that the portion of the 800 demand for capital goods devoted to producing these particular capital goods is also 16 percent—namely, 128, which last is equal to .16 times 800. In the same way, the value of the labor employed to produce the capital goods of one degree of remove from consumers' goods is 16, which, of course, is 16 percent of the 100 total demand for labor. Thus, factors of production with a combined value of 144 at two degrees of remove from the production of consumers' goods produce capital goods of one degree of remove from the production of consumers' goods, which latter capital goods have a value of 160.

In every year, there is a demand for capital goods and labor of the second degree of remove, side by side with the demand for capital goods and labor of the first degree of remove. In every year, a second downward and leftward sloping arrow runs from the 128 and 16 of expenditure for factors of production of the second degree of remove, to the 160 of sales proceeds brought in, in the following year, by the capital goods of the first degree of remove that they serve to produce.

Carrying the same reasoning a step further, the 128 of demand for capital goods of the second degree of remove constitutes 12.8 percent of the total demand for goods in each year ($128/1,000$). Thus 12.8 percent of the demand for capital goods and labor in each year can be assumed to be devoted to the production of capital goods of the second degree of remove in the following year. On this basis, the third component of the demand for capital goods, D_{K3} , turns out to be 102.4 (viz., .128 times 800). The accompanying demand for labor at this point of three degrees of remove from the production of consumers' goods is, of course, 12.8, which is 12.8 percent of 100.

Thus, 115.2 is the total demand for factors of production at this, third degree of remove, and it is the cost of producing the 128 worth of capital goods that become available in the following year at the second degree of remove from the production of consumers' goods.

Finally, the table shows that at four degrees of remove from the production of consumers' goods, namely, in the column labeled D_{K4} , 81.92 worth of capital goods and 10.24 worth of labor are employed to produce the 102.4 worth of D_{K3} capital goods that will become available in the following year at three degrees of remove from the production of consumers' goods. (These amounts, of course, represent 10.24 percent of the respective 800 and 100 demands for capital goods and labor, which percentage corresponds to the percentage of 1,000 monetary units of total sales revenues that is constituted by the 102.4 monetary units of sales revenues represented by D_{K3} .)

In every year, capital goods and labor of all degrees of remove exist side by side and are used to produce capital goods of one degree of remove less for the following year; or, in the case of capital goods and labor which are themselves merely of one degree of remove, consumers' goods for the following year. At all degrees of remove in the table, arrows trace the connection to the next, lower degree of remove in the following year and thereby show how the demand for factors of production at any given degree of remove serves to bring in sales revenues greater than itself.

Thus, far from the entire outlay for factors of production being charged against the sale of consumers' goods, only that portion is charged which corresponds to the *fraction* of the total demand for goods constituted by the demand for consumers' goods specifically. Thus, in this case, not the full 900 of demand for factors of production is charged to the production of consumers' goods, but only 20 percent of that 900. The portion of the outlay for factors of production made by the producers of consumers' goods which is constituted by their demand for capital goods (160 out of 180) in turn constitutes the sales receipts of the producers of these capital goods. The producers of these capital goods in turn must make outlays for factors of production, and, in the present case, the principal portion of their outlays is for capital goods, and constitutes the sales receipts of further producers of capital goods, and so on. It is only in this manner, by cumulating the demand for capital goods made by producers at different degrees of remove from the production of consumers' goods, that the outlays for factors of production by business exceed the demand for consumers' goods.

From a mathematical perspective, the right-hand portion of Table 17-2 represents an infinite series that is repeated over and over again in succeeding rows of the table. Starting with the second term of this series in the

first row, namely, the term under the heading D_{K1} , and taking each further term to the right representing the outlays for capital goods of progressively greater degrees of remove from the production and sale of consumers' goods, it is clear that each such term is covered by a larger volume of sales revenues for the corresponding product, which is represented by the term of the series just to the left, one row down. (In the case of the demand for capital goods under the head D_{K1} , the sales revenues represented by the term to the left one row down are, of course, the demand for consumers' goods, D_C .)

It should be understood that the assumption made in the preceding discussion that the demand for capital goods and labor is always strictly proportional to the sales revenues brought in, and that the two respective demands are always in the same proportion to each other, is not necessary. It has been made for the purpose of simplification. Actually, technical considerations would make the demands for capital goods and labor stand in different proportions both to sales revenues and to each other at different stages of production. Such differences, however, do not affect anything of significance. From the perspective of the present discussion, they are mutually offsetting.

It should also be realized that, beyond a point, production at the higher degrees of remove is physically indistinguishable from production simultaneously going on at lower degrees of remove. For example, it is a matter of such things as the output of steel serving in the construction of steel mills, some portion of whose output serves in the construction of further steel mills, and so on and on, indefinitely. Production at the higher degrees of remove becomes a matter of indefinite duplications of processes of production simultaneously going on at lower degrees of remove. That is, beyond a point, it differs from processes of production simultaneously being carried on at lower degrees of remove only in that its ultimate targets are more remote—for example, the steel mills that will be built from steel produced in steel mills constructed with this year's steel versus simply the steel mills that will be built with this year's steel. Thus, a rise in the economic degree of capitalism and in capital intensiveness represents an increase both in the extent to which physically different processes of production requiring the more remote employment of capital goods and labor can be implemented and in the proportions in which physically identical processes of production are devoted to temporally more remote ends.

Consumption as the Purpose of Production and the Progressive Production of Consumers' Goods Over Time

Ironically, Table 17–2 demonstrates that, if qualified by the word “ultimately,” Hobson was right when he said

that the only use of capital is to aid in the production of “‘utilities and conveniences’ for consumers.” His error was in thinking that this was incompatible with the demand for factors of production being greater than the demand for consumers' goods.

Table 17–2 shows that the entire outlay for factors of production in any year, even though enormously larger than the demand for consumers' goods (900 vs. 200) ultimately serves entirely in the production of consumers' goods, and is ultimately chargeable entirely to the sale of consumers' goods. However, the consumers' goods in question are certainly not those just of the next year. Rather, they are the consumers' goods that will come into existence to a progressively greater extent with the passage of time. For example, the D_{K1} of Year N , and its associated demand for labor, is the only part of the outlay for factors of production in Year N that directly serves in the production of consumers' goods—specifically, in the production of the consumers' goods that become available in Year $N+1$. This outlay is directly chargeable to the sale of consumers' goods. However, the D_{K2} of Year N , and its associated demand for labor, indirectly serve in the production of consumers' goods—the consumers' goods that will become available in Year $N+2$. These outlays are indirectly chargeable to the sale of those consumers' goods, for they serve in the production of the capital goods that become available in Year $N+1$ and which in turn serve in the production of the consumers' goods of Year $N+2$. Arrows trace the path from D_{K2} and its associated demand for labor in Year N to the sale of consumers' goods two years later.

In the same way, the D_{K3} of Year N , and its associated demand for labor, indirectly serve in the production of the consumers' goods of Year $N+3$; the D_{K4} of Year N , and its associated demand for labor, indirectly serve in the production of the consumers' goods of Year $N+4$; and, finally, the D_{Kn} of Year N , and its associated demand for labor (neither of which are shown in the table), indirectly serve in the production of the consumers' goods of Year $N+n$. Again, arrows trace the paths. All outlays for capital goods and labor are, to repeat, *ultimately* for the sake of producing consumers' goods. It is only a question of how far in the future those consumers' goods lie.⁸⁹

Thus, in Table 17–2, the cumulative demand for capital goods that takes place in Year N and that contributes to the production of consumers' goods within four years from Year N is $160 + 128 + 102.4 + 81.92$, or 472.32 out of an eventual total of 800. This is the sum of the demands for capital goods in Year N under the column headings D_{K1} through D_{K4} . The cumulative demand for labor that contributes to the production of consumers' goods within four years from Year N is $20 + 16 + 12.8 + 10.24$, or 59.04

out of an eventual total of 100. This is the sum of the associated demands for labor in *Year N* under the column headings D_{K1} through D_{K4} . The combined cumulative demand for capital goods and labor together is thus 531.36 out of an eventual total of 900. If the number of years beyond *Year N* under consideration were increased from four to eleven, then it would be found that more than 90 percent of the demand for capital goods and labor in *Year N* would be accounted for as contributing to the production of consumers' goods. This, indeed, is shown in Table 17-3.

Table 17-3 compresses the format of Table 17-2. It shows one-dimensionally what the former shows two-dimensionally. Thus, it is able to depict the expenditures of a larger number of years in the same space. It shows the contribution of the labor and capital goods of *Year N* to the production of consumers' goods through *Year N+11*, both year by year and cumulatively.

Column one of the table is the series of years *N* through *N+11*. Column two lists one through eleven degrees of remove from the production of consumers' goods, with each degree of remove representing a year

of time—the time between *Year N* and the year shown in column one. The expenditures shown in columns three, four, and five represent the expenditures made in *Year N*—at the degree of remove shown in column two—on behalf of the production of consumers' goods that become available in the corresponding year in column one.

Thus, for example, for *Year N+5* the table shows that the expenditure for capital goods that is made in *Year N* on behalf of the consumers' goods that will become available in *Year N+5* is 65.54, while the associated demand for labor is 8.19; the summation of these two figures, shown in the last column, is 73.73. Similarly, for *Year N+10* the expenditure for capital goods that is made in *Year N* on behalf of the consumers' goods that will become available in *Year N+10* is 21.47, while the associated demand for labor is 2.68; the summation of these two figures is 24.15, which, as in the previous case, is shown in the last column.⁹⁰

When these expenditures for factors of production on behalf of consumers' goods that will come into existence over the years *N+1* through *N+11* are cumulated, it turns out that 91.40 of the 100 total demand for labor serves

Table 17-3
The Demand for Factors of Production in *Year N* and Its Cumulative Contribution to the Production of Consumers' Goods in the Future

<i>Future Year</i>	Degree of Remove of <i>Year N</i> from Future Year	Demand for Capital Goods in <i>Year N</i> on Behalf of Consumers' Goods of Given Future Year	Demand for Labor in <i>Year N</i> on Behalf of Consumers' Goods of Given Future Year	Total Demand for Factors of Production in <i>Year N</i> on Behalf of Consumers' Goods of Given Future Year
<i>N+1</i>	1	160.00	20.00	180.00
<i>N+2</i>	2	128.00	16.00	144.00
<i>N+3</i>	3	102.40	12.80	115.20
<i>N+4</i>	4	81.92	10.24	92.16
<i>N+5</i>	5	65.54	8.19	73.73

<i>N+8</i>	8	33.55	4.19	37.75
<i>N+9</i>	9	26.84	3.36	30.20
<i>N+10</i>	10	21.47	2.68	24.16
<i>N+11</i>	11	17.18	2.15	19.33
	Cumulative Demands:	731.27	91.40	822.67
...	Eventual Cumulative Demands:
<i>N+n</i>		800.00	100.00	900.00

directly or indirectly in the production of consumers' goods and that 731.27 of the 800 total demand for capital goods serves directly or indirectly in the production of consumers' goods. Thus, 822.67 of the 900 total demand for factors of production serves directly or indirectly in the production of consumers' goods that will become available within eleven years.⁹¹ This figure and the two figures from which it is derived all represent something more than 90 percent of the respective total demands for labor, capital goods, and factors of production in general. If the cumulation process were concluded with *Year N+10* rather than *Year N+11*, the accumulated sums would represent something less 90 percent of the respective total demands.

Thus conditions in Tables 17-2 and 17-3 are essentially similar to the conditions previously described in connection with Figures 17-2 and 17-3, where it was found that in both cases 90 percent of the factors of production in existence in a base year contributed to the production of consumers' goods within some period of years—less than four years in the case of Figure 17-2, and more than four years in the case of Figure 17-3.⁹² Table 17-3 confirms that in all cases, irrespective of the demand for capital goods relative to the demand for consumers' goods, the entire supply of factors of production in existence in any given period of time always ultimately serves to produce consumers' goods and only consumers' goods. The effect of a rise in the demand for capital goods relative to the demand for consumers' goods is merely to increase the time interval which must elapse before any given percentage of the existing supply of factors of production results in the production of consumers' goods. All that is involved in the present, deliberately extreme case is a substantially longer average period of production. Thus only by *Year N+11* will more than 90 percent of the factors of production available in *Year N* have contributed to the production of consumers' goods.

What must always be kept in mind, however, is that even though all production is ultimately for the sake of the production of consumers' goods, the length of the period of time which must elapse before any given percentage of the production of a given base year results in the production of consumers' goods is of critical importance, insofar as that time span is determined by the extent of concentration on the production of capital goods. In the case of Tables 17-2 and 17-3, as opposed to that of Figure 17-2, four years elapse, and still the fraction of the capital goods and labor of *Year N* which cumulatively result in the production of consumers' goods is below 60 percent ($531.36/900$). Eleven years must elapse before it exceeds 90 percent. Under different conditions, this figure could be 90 percent (or even more) in just a

single year. This last case would be approached if each year the relative magnitudes of D_C and D_K were the reverse of those in the present example. If D_C were 800 and D_K were 200, then 80 percent of the capital goods and labor of *Year N* would have served in the production of consumers' goods by *Year N+1*, and a further 16 percent by *Year N+2*.

Such differences make all the difference in the world. In an economy in which 80 or 90 percent of the capital goods and labor are used up in producing consumers' goods in just one year, production will be in a radically inferior state in comparison with one in which a decade or more must elapse before such a high percentage is achieved. In the latter economy, the production of each year is devoted heavily to the production of the means of production for the following year and for more remote future years. In the former economy, the production of each year is devoted only minimally to the production of means of production for the following year and more remote future years. Thus, the ability to implement technological advances will be radically different in the two economies, with the economy enjoying the longer average period of production possessing enormous advantages over the one with the shorter average period of production.⁹³ In its case, the likely outcome will be that its total ability to produce and accumulate capital will rise from year to year, with the result that it will enjoy economic progress and rising prosperity.

In contrast, in the economy with the radically shorter period of production, the result at best must be stagnation at an extremely low level. Indeed, insofar as an economy's average period of production is first in the process of becoming substantially shorter, the result must be capital decumulation and a falling ability to produce from year to year, in other words, economic retrogression and worsening poverty. This is because an economy suffering a substantial decline in its average period of production will not be able to maintain technologies it has previously implemented insofar as they require the employment of substantial quantities of means of production significantly in advance of the completion either of the ultimate consumers' goods or, indeed, of the production of the relevant capital goods. Economic retrogression must go on until the methods of production employed require so little in the way of capital goods that the capital goods can all be replaced just by devoting to their production the modest share of the meager output that it is possible to devote to their production in the conditions of the case.

Tables 17-2 and 17-3 show that the entire outlay for factors of production in any given base year can be regarded as covered by receipts from the sale of consumers' goods, provided only that one looks to the production

of consumers' goods over an extended enough number of years. Thus, in Table 17-2, the outlays for capital goods and labor under the headings D_{K1} through D_{K4} in *Year N* can be regarded as covered by a total of 800 of receipts from the sale of consumers' goods—viz., by 200 of receipts from the sale of consumers' goods in each of the four years $N+1$ through $N+4$. By the same token, the outlays for capital goods and labor in *Year N* that would appear in a table wide enough to contain columns for D_{K1} through D_{K11} could be regarded as covered by the 2,200 of receipts from the sale of consumers' goods brought in over the years $N+1$ through $N+11$.

This understanding should not give rise to any new worry that now perhaps business somehow appears inexplicably profitable, with 2,200 of consumer sales receipts covering less than 900 of demand for factors of production. In each year, aggregate profits are no more than 100. In each year, the 200 of receipts from the sale of consumers' goods covers—accordion-like—the outlays for factors of production made not just in any one prior year, but in a whole series of prior years extending back into the indefinite past. For example, the 200 of receipts from the sale of consumers' goods in *Year N+4* covers far more than the demand for capital goods and labor made just in *Year N*. It covers successively the 160 of demand for capital goods and 20 of demand for labor made under the heading D_{K1} in *Year N+3*, the 128 of demand for capital goods and 16 of demand for labor made under the heading D_{K2} in *Year N+2*, and the 102.4 of demand for capital goods and 12.8 of demand for labor made under the heading D_{K3} in *Year N+1*, as well the 81.92 of demand for capital goods and 10.24 of demand for labor made under the heading D_{K4} in *Year N*. Indeed, the 200 of demand for consumers' goods made in *Year N+4* covers an indefinitely large number of further expenditures for capital goods and labor extending back indefinitely into years prior to *Year N*.

A relatively small amount of demand for consumers' goods is able profitably to cover such a large demand for capital goods and labor—a demand much larger than itself—precisely because, as repeatedly shown, the demand for capital goods is subdivided into successive, component parts, each one progressively more remote from the production of consumers' goods. These parts stand behind one another and can, in effect, be fitted into one another, along with their accompanying demands for labor. That is, each preceding part of the demand for capital goods is smaller than the one it precedes, just as the first and largest component part of the demand for capital goods is smaller than the demand for consumers' goods, which it precedes. And thus each prior component part is able to represent sales revenues that profitably cover the next, more remote component part along with

its accompanying demand for labor.

As illustration, the situation in Tables 17-2 and 17-3 is that 200 of demand for consumers' goods in any one year covers 900 of demand for factors of production made over an indefinitely large number of prior years. In the first instance, it covers only 160 of demand for capital goods and 20 of demand for labor—viz., the demands for capital goods and labor made at one degree of remove the year before. In the second instance, it covers the 128 of demand for capital goods and 16 of demand for labor that were made at two degrees of remove, two years before. This latter demand for capital goods and labor was directly covered by the 160 of demand for capital goods at one degree of remove. (In effect, the 128 and 16 stand behind the 160, and are covered by it, while the 160 and a further 20 of demand for labor stand behind the 200 of demand for consumers' goods and are covered by it.) The same process extends backward prior to the 128 and 16, to an indefinite number of still earlier years each of whose demands for capital goods and labor are covered by a demand for capital goods that is one year less removed from the demand for consumers' goods.

Tables 17-2 and 17-3 depict a kind of lining-up and fitting-in process as it were, by which successive components of the demand for factors of production at further degrees of remove are covered by the demand for capital goods at one degree of remove less, and ultimately by the demand for consumers' goods. A good analogy is provided by a set of luggage of the type in which all of the pieces can be successively packed into the next-larger piece, with the result that all of them ultimately fit into the single, largest piece. For example, an attaché case fits inside an overnighter, which fits inside a one-suitcase, which, in turn, fits inside a two-suitcase, which, finally, fits inside a three-suitcase. The three-suitcase is the counterpart of the demand for consumers' goods, while the remaining, successively smaller pieces are the counterpart of demands for capital goods at successive degrees of remove. The largest piece, the three-suitcase, is large enough to contain all of the smaller pieces, even though the combined volume of the four smaller pieces is substantially greater than the volume of the largest piece. This is exactly how it is when the demand for capital goods, or capital goods plus labor, is greater than the demand for consumers' goods. As in Table 17-3, the demand for labor and capital goods at the eleventh degree of remove fits into—viz., is profitably covered by—the demand for capital goods at the tenth degree of remove, which, in turn, together with its associated demand for labor, fits into the demand for capital goods at the ninth degree of remove, and so on until the demand for capital goods and labor at the first

degree of remove fits into the demand for consumers' goods.

The suitcase analogy can shed light on other important aspects of the process. It helps to make clear exactly how it is possible—and, indeed, under the conditions of a fixed quantity of money and total volume of spending, absolutely necessary—that *in order for the demand for capital goods to rise, the demand for consumers' goods must fall*. For if there is a fixed total amount of material that is available for the production of all the pieces of luggage in the set, then it is clear that if all of this material were devoted to the production of a single, very large, largest piece, say, to a five- or six-suiter, then absolutely no material would be available for the production of the smaller pieces. In order to have material available for the production of the smaller pieces, it is absolutely essential that the amount of material devoted to the largest piece be strictly limited. We know, of course, that it is limited, and that, nevertheless, there is no problem of its being made too small to contain all the other pieces at the same time, because each of those other pieces successively fits into the next-larger one. In just the same way, with a fixed quantity of money and total volume of spending, in order for there to be a greater demand for capital goods, the demand for consumers' goods must be correspondingly less. And however great the demand for capital goods may become relative to the demand for consumers' goods it will all still “fit into” the demand for consumers' goods because it consists of separate portions which successively “fit into” each other.

The Ratio of Demands Between Stages

The luggage analogy can be carried further. It shows not only that as the size of the largest piece in the set is reduced, material becomes available to enlarge the size of all the remaining pieces, but that the greater total volume of space now represented by the smaller pieces fits into the smaller volume of space now represented by the largest piece, by virtue of a change in the ratio between the size of the succeeding pieces. At the most extreme, the largest piece requires all of the material and has the maximum possible volume, leaving no material and no volume whatever for the smaller pieces. One can think of this case as the five- or six-suiter followed by a second piece *zero percent* as large. When the size of the largest piece is reduced to that of a three-suiter, the next-largest piece becomes perhaps two-thirds as large (the two-suiter), followed by a third largest piece (the one-suiter) having a size perhaps half as large as the second largest piece, and so on. Thus, as the size of the largest piece is reduced, it becomes capable of containing the growing total volume of space contained in the further pieces by virtue of a rise in the size ratios between the successive pieces.

It is essentially the same when it concerns the demand for consumers' goods and the demand for capital goods, only more so. The demand for consumers' goods can fall and the demand for capital goods can rise at the very same time, and yet the demand for capital goods is always profitably covered by the demand for the product, whether further capital goods or consumers' goods. All that is necessary is a change in the ratio between the demand for the product at each stage and the demand for the capital goods to produce the product. This fact can be highlighted by comparing the present case of a 200 demand for consumers' goods and 800 demand for capital goods, with the case back in Figure 16–2 of a 500 demand for consumers' goods and a 500 demand for capital goods.

In the present case, the demand for capital goods at one degree of remove from the demand for consumers' goods is 160—80 percent of the demand for consumers' goods. In the conditions of Figure 16–2, the demand for capital goods at one degree of remove from the demand for consumers' goods is 250—50 percent of the demand for consumers' goods. It follows that if the economic system made a transition from the conditions of Figure 16–2 to those of the present case, not only would the demand for consumers' goods fall, but also the demand for capital goods at one degree of remove would fall, because the fall in demand for consumers' goods would be so very great. But it should be noted that this fall in demand for capital goods at one degree of remove would be much smaller than the fall in demand for consumers' goods. While the fall in demand for consumers' goods is 60 percent (500 to 200), the fall in demand for capital goods at one degree of remove is only 36 percent (250 to 160).

And then, which may appear to be astonishing to some people, it turns out that from two degrees of remove on, the demand for capital goods in the present case begins to further and further *surpass* the demand for capital goods in the conditions of Figure 16–2, despite the fact that the demand for consumers' goods is so much lower in the present case. For at two degrees of remove, the demand for capital goods in the present case is 128 (80 percent of 80 percent of 200), while the demand for capital goods at this degree of remove in the conditions of Figure 16–2 is only 125 (50 percent of 50 percent of 500). At three degrees of remove, the difference is that between 80 percent to the third power times 200, and 50 percent to the third power times 500—viz., between 102.4 and 62.5—which is a much wider difference in favor of the present case.

Indeed, the difference between the present case and that of Figure 16–2 can be expressed as the difference between two infinite series, the first term of one of which is 200 and the first term of the other of which is 500, and

with each succeeding term being 80 percent of the preceding term in the one case and only 50 percent in the other. When seen in this way, it becomes obvious that very quickly the succeeding terms become relatively larger in the case in which the first term—the demand for consumers' goods—is smaller, and then widen their lead with each succeeding term. This fact is illustrated in Table 17–4, which compares the demand for capital goods and labor in the present case with that of Figure 16–2 for eleven degrees of remove. The table shows that starting with the sixth degree of remove even the demand for labor in the present case is greater than in the conditions of Figure 16–2, despite the fact that the total demand for labor is only 100 in the present case while it was 300 in the conditions of Figure 16–2.

The general principle can be stated as follows: When the demand for consumers' goods falls and the demand for capital goods rises, the process represents the transition from an infinite series with a relatively high first term followed by a relatively rapid rate of diminution in the subsequent terms, to a new infinite series with a correspondingly lower first term and a correspondingly diminished rate of diminution in the subsequent terms. When understood in this way, it becomes obvious that in the conditions of an invariable money, in which the sum of all terms combined will always be the same, such as 1,000 monetary units, the sum of all terms beyond the first—viz., the demand for capital goods—is higher, the lower is the first term, which first term, of course, is the demand for consumers' goods.

It is worth noting a related fact. Namely, that while in the present case something over 90 percent of the total demand for factors of production serves directly or indirectly in the production of consumers' goods within eleven degrees of remove, the percentage for Figure 16–2 within the same number of degrees of remove is virtually 100 percent. The significance of this is that provision for more remote future periods continues to be substantial in the one case, after it is virtually exhausted in the other.

More on the Average Period of Production

The preceding discussion, particularly the application of infinite series, raises questions concerning the length of the average period of production. The average period of production can be understood, quite correctly, as covering a period of potentially unlimited length. To some very limited extent, the consumers' goods being produced today owe their existence to capital goods and labor employed at the time of Caesar, indeed, to capital goods and labor employed in the very earliest periods of human history. And to some extent that is also very limited, the capital goods and labor in existence today

will contribute to the production of consumers' goods in the years 5,000, 10,000, and beyond.

This is so because with the exception of the very first consumers' goods, which were appropriated directly from nature, such as nuts and berries growing wild on trees, all consumers' goods have been produced with the aid of capital goods. And with the exception of the very first capital goods, which were also appropriated directly from nature, such as rocks and sticks, all capital goods have been and will continue to be themselves produced with the aid of capital goods. Thus, the indirect contribution of capital goods to the production of consumers' goods spans a period of time that is virtually coextensive with man's presence on earth and, as far as the future is concerned, a number of degrees of remove that has no fixed limit.

Obviously, the contribution of the past to the present and of the present to the future declines exponentially as one extends the period of time under consideration. And for this very reason, I have followed the procedure of selecting a limit, in the form of how long a period of time must elapse for a given percentage of the means of production in existence in a base period to have directly or indirectly contributed to the production of consumers' goods. Applying that approach, the length of the average period of production becomes sharply delimited and independent of the absolute length of man's existence on earth either up to now or at any point in the future.⁹⁴

Whether one takes the contribution of 90 percent of the factors of production in existence in a base period or 99 percent of such factors of production, or whatever percentage, the period of time which must elapse before any such percentage contributes to the production of consumers' goods is strictly delimited, and always remains the same, so long as the relative production of consumers' goods and capital goods is the same.

The method of measuring the average period of production employed thus far is very easy to apply in the highly simplified conditions which have been assumed, namely, that all capital goods in existence in the beginning of a year are used up in that very same year and that a year is the period of time which elapses in all stages of production. Conditions are far more complex in reality, of course. Thus, an alternative, but still relatively simple method may be appropriate for conceiving the length of the average period of production.

This is the concept of *how long a time would have to elapse for the wage payments made in a given period to grow to equality with the prevailing level of spending for consumers' goods when compounded at the rate of one plus the prevailing rate of profit*. To illustrate the concept in the conditions of Figure 16–2, it means the time that must elapse for 300 of wage payments to grow to equality

Table 17-4
Comparison of the Present, Extreme Case With That of Figure 16-2

11	17.18	2.15	19.33	0.24	0.15	0.39
Cumulative Demands:	731.27	91.40	822.67	499.76	299.85	799.61
...
Eventual Cumulative Demands:	800.00	100.00	900.00	500.00	300.00	800.00

*Summing the two columns to the left may not equal this column because of rounding.

with 500 of demand for consumers' goods at one plus the 11.11 percent rate of profit that prevails in Figure 16-2. In the case considered in Tables 17-2 and 17-3, it means the time that must elapse for 100 of wage payments to grow to equality with 200 of consumer spending at the implied rate of profit of 5.26 percent. (This last is the rate of profit implied by a 100-amount of profit—which is equal to the 100 of net consumption in the case described by the tables—divided by 1,900 of capital, which latter equals 900 of productive expenditure plus 1,000 of cash in the hands of business. Thus, the rate of profit here is

the same as the rate of profit that prevails in the conditions described earlier in Figure 17-1.)

The basis for this method of measurement of the average period of production is the fact that the price of every product is ultimately equal to a sum of profits and wage payments extending into the past, with profits compounding on the wage payments at the prevailing rate of profit, as the process of production successively approaches the present.⁹⁵ The lower is the rate of profit and the greater is the ratio of the demand for consumers' goods to the demand for labor, the longer is the average

period of production. The higher is the rate of profit and the smaller is the ratio of the demand for consumers' goods to the demand for labor, the shorter is the average period of production. In the specific cases of Figure 16-2 and that of Tables 17-2 and 17-3, for example, the average period of production turns out to be 4.89 and 13.5 years respectively, when computed in this way.⁹⁶

The reason that the length of time required for the current payment of wages to grow to equality with a sum equal to the prevailing level of demand for consumers' goods, at the currently prevailing rate of profit, can be taken as the measure of the length of the average period of production is as follows. If an invariable money prevailed for an indefinitely long period of time, along with constancy in the ratios between the demands for capital goods and consumers' goods and capital goods and labor, today's demands for consumers' goods and labor could be taken as representing the demands for consumers' goods and labor in every future year, and today's rate of profit could be taken as representing the rate of profit for the indefinite future. Today's wage payments would then be launched, in effect, toward segments of future demands for consumers' goods which in toto equalled today's demand for consumers' goods, and they would be launched with continuing "velocities," so to speak, equal to the prevailing rate of profit. The average time required for n segments of this year's wage payments to grow to equality with n segments of aggregate consumer demand collectively equal to the aggregate consumer demand of this year, at the currently prevailing rate of profit, is approximated by the time required for the sum of all wage payments this year to grow to equality with a sum equal to this year's consumer demand, at the currently prevailing rate of profit. Thus, to use the case of Table 17-3 as illustration, the average time required for the sum of $20 + 16 + \dots = 100$ of wage payments this year to grow at a 5.26 percent rate of profit to equality with $20(1.0526) + 16(1.0526)^2 + \dots = 200$, is approximated by the time required for 100 to grow to 200 at a 5.26 percent rate of profit, namely, 13.5 years.

To adapt this technique to the conditions of an increasing quantity of money and volume of spending, it is necessary to estimate the influence of this factor on the prevailing rate of profit and then to subtract the estimated monetary component from the rate of profit before performing the calculation.

A Rise in the Demand for Capital Goods and Fall in the Demand for Consumers' Goods: The Cross-Hatching of Production

The belief that the demand for consumers' goods by itself must cover the outlays of business for factors of production is so deep-rooted that still further discussion

demonstrating the contrary is called for. Therefore, let us consider a concretized illustration of a drop in consumption. Let us take two industries producing consumers' goods as representing all industries producing consumers' goods. The automobile and air-conditioning industries will serve. We assume that the consumption of the owners and creditors of the automobile industry manifests itself in a demand for air conditioners, the product which we employ to represent all consumers' goods which the producers of automobiles might purchase. And we assume that the consumption of the owners and creditors of the air-conditioning industry takes the form of a demand for automobiles, the product which we employ to represent all consumers' goods which the producers of air conditioners might purchase.

Now let us imagine that the businessmen and capitalists of the automobile industry reduce their consumption. Must this adversely affect the producers of air conditioners? Not at all. For the funds which the businessmen and capitalists of the automobile industry previously employed in their own consumption can now be employed in the purchase of products to be employed in their business. Air conditioners can be installed in the automobiles they manufacture, or if not air conditioners themselves, then some other product which can be produced by the air-conditioning industry and which is of use in the production of automobiles. Thus, the total sales revenues of the air-conditioning industry are unchanged. All that has happened is that now the air-conditioning industry concentrates less on the production of consumer air conditioners and devotes more of its resources to the production of something employed in the manufacture of automobiles, such as automobile air conditioners. Thus, there has simply been a shift from consumption expenditure to productive expenditure on the part of the businessmen and capitalists of the automobile industry, and a corresponding shift in the production activities of the producers of air conditioners in response to a change in demand.

If no objection can be made to our treatment thus far, then, certainly, none can be made to the assumption that instead of the consumption of the businessmen and capitalists of the automobile industry falling, while that of the businessmen and capitalists of the air-conditioning industry remains unchanged, the reverse occurs. For then it would simply be a matter of the businessmen and capitalists of the air-conditioning industry buying fewer pleasure cars and correspondingly more trucks (or cars) to be employed in their business. In this case, the automobile industry would concentrate less on the production of consumers' goods and more on the production of capital goods. This time, there would be a shift in the demand of the businessmen and capitalists of the air-con-

ditioning industry and a corresponding shift in production on the part of the businessmen and capitalists of the automobile industry. As in the case of the air-conditioning industry a moment ago, the total sales revenues of the automobile industry would remain the same.

What is present in both of these cases is the very important physical fact that every capitalist who reduces his consumption and expands his purchases of capital goods thereby benefits his customers to precisely the same degree. This is because the buyers of his products spend no more in the purchase of those products, while more has been spent in their production. The capitalist who so acts passes on to his customers, in the product he sells, the contribution of the factors of production which otherwise would have been employed in producing for his own consumption. This is what happens when the producers of automobiles reduce their consumption. They provide their customers with more and better automobiles, because instead of buying products to be consumed, they now possess the financial means of buying better-quality materials and more and better accessories or components or more and better plant and equipment; and to their increased financial means corresponds the increased physical means of producing these products, owing to the release of factors of production from the production of consumers' goods. Exactly the same kind of result occurs when the manufacturers of air conditioners reduce their consumption: not only do they then have additional financial means of buying more and better capital goods, but also to their greater financial means correspond the increased physical means of producing those capital goods, owing to the release of factors of production from the production of consumers' goods.

It is when the consumption of both sets of businessmen and capitalists is assumed to drop simultaneously that difficulties are imagined. Yes, it will be said, the businessmen and capitalists of the automobile industry can reduce their consumption and employ more funds in their business, because the demand for automobiles has not fallen. Alternatively, the businessmen and capitalists of the air-conditioning industry can reduce their consumption and employ more funds in their business, because the demand for air conditioners has not fallen. But both together? That, it will be claimed, is impossible, because it means that the demand for the products of the two sets of producers has fallen and they are being asked to spend more at the very time that the revenues they derive from their products are less.

Nevertheless, of course, it is possible. And the revenues they derive are not any less. The automobile industry, instead of producing merely more and better automobiles by virtue of its increased demand for capital goods, now produces more and better automobiles *and*

more and better trucks, or other capital goods. And the air-conditioning industry, instead of producing merely more and better consumer air conditioners by virtue of its increased demand for capital goods, now produces both more and better consumer air conditioners *and* more and better capital goods, such as air conditioners for automobiles and trucks.

Moreover, each industry's improved production of capital goods then serves the production of the other not only with respect to the other's production of consumers' goods, but also with respect to the other's *further production of capital goods*. The automobile industry's improved production of trucks or other capital goods resulting from its increased input of capital goods, serves the air-conditioning industry not only in the production of consumer air conditioners, but *also* in the production of the capital goods produced by the air-conditioning industry, thereby making possible still further improvements in the production of both types of products by the air-conditioning industry. By the same token, the air-conditioning industry's improved production of capital goods resulting from its increased input of capital goods, serves the automobile industry not only with respect to its output of cars, but also with respect to its output of trucks or other capital goods, thus making possible still further improvements in the automobile industry's production of capital goods as well as consumers' goods. The improvements of each in the production of capital goods, in serving to improve the other's ability to produce not only consumers' goods but also capital goods, creates the possibility of endless improvement through endless feedback, with the other's improved production of capital goods serving in the further improvement of one's own production, including one's further production of capital goods, and thus in the still further improvement of the other's capital goods as well as consumers' goods.

There are three things involved: (1) A shift in the demand of each party from consumers' goods to capital goods, causing a corresponding shift in the production of the other. (2) An increase in the production of each party resulting from his possession of the additional capital goods produced by the other. (3) A disposition of the enlarged productive ability of each party in favor of capital goods, conforming to the change in demand on the part of the other.

In response to the other's change in demand, each party shifts from the production of consumers' goods to the production of capital goods. And as the result of his own change in demand, each party employs more funds—and more real resources—in producing both his consumers' goods *and* his capital goods than if the demand of the other party alone had changed. That the demand of the other party has changed results in the fact that one not only employs additional capital, but also employs a

correspondingly larger proportion of one's additional capital in the production of further capital goods.

What happens as the result of this process is that production becomes cross-hatched, as it were, or more cross-hatched. That is, part of the output, or a greater part of the output, of each of the industries serves as capital goods to the other and enables the other, in turn, all the better to produce not only consumers' goods but also capital goods and thus to supply it with still more and still better capital goods, as well as its wage earners and businessmen and capitalists with more and better consumers' goods. The result in our example is that the automobile industry is able to carry on its production both of consumers' goods and of capital goods with the aid of more of the output of the air-conditioning industry, and the air-conditioning industry is able to carry on its production both of consumers' goods and of capital goods with the aid of more of the output of the automobile industry. And the output of each that serves the other benefits from a greater prior contribution of the output of the other.

What is true of this illustration based on two industries is true of the economic system generally. The greater is the demand for capital goods relative to the demand for consumers' goods in the economic system, the larger is the fraction of the output of the economic system that takes the form of capital goods and the larger is the fraction of the output of the economic system that enters into the production of capital goods. Both capital goods and consumers' goods have more prior output going into them, as well as more of current output being in the form of capital goods. The consequence of the expanded and improved production of capital goods is the possibility of endless improvement in the further production of capital goods and thus of endless improvement in the production of consumers' goods.

These results, of course, are fully confirmed by examining the data of Figure 17-1 as the transition is made to a more capital intensive economy, and thereafter. The economic progress of Figure 17-1 results from the relatively greater concentration on the production of capital goods and the employment of more capital goods in the production of further capital goods.

An implication of the preceding discussion is that the perception, over the last several decades, of flimsy and shoddy products—for example, thin walls in newer buildings compared with those constructed before World War II—as a reflection of less going into the products, is correct. Such phenomena are manifestations of a less-capital-intensive economy today in comparison with the past. Less *is* going into products, not because of any greater personal consumption on the part of businessmen

and capitalists, however, but because taxation, budget deficits, and inflation, to finance the consumption of the government, are diverting factors of production from the production of capital goods, which contribute to further production, to the production of consumers' goods for the government and those to whom the government gives money.

12. More on Why Savings Cannot Outrun the Uses for Savings

In the last chapter, I showed how the process of net investment and capital intensification operate to eliminate any possibility of the persistence of negative net consumption, which might be imagined to stem from saving on the part of wage earners.⁹⁷ Here, it is appropriate to bring forward additional considerations in support of the proposition that in the long-run at least net consumption must always be significantly positive and thus that a significantly positive rate of profit must exist even under the conditions of an invariable money.

Capital Intensiveness and Land Values

The disappearance of any negative net consumption on the part of wage earners is absolutely guaranteed by the fact that as the rate of profit on capital approaches zero, the degree of capital intensiveness that becomes economically worthwhile literally approaches infinity. Thus there is room in the economic system for incalculably more savings and capital than wage earners or anyone else can ever accumulate, and thus certainly room for wage earners to accumulate enough savings and capital relative to their incomes to put an end to any negative net consumption on their part.

The degree of capital intensiveness that pays approaches infinity as the rate of profit approaches zero, if for no other reason than because of the effect of a zero rate of profit on the value of land. (In addition, of course there is the fact that in such conditions it would pay to carry the use of capital to the point where absolutely no further reductions in cost of production or improvements in the quality of products could be achieved by the use of more capital, which itself would entail the existence of far more capital than could ever be accumulated.⁹⁸) At a zero rate of profit, the value of land would literally be infinite. Indeed, the value even of a single parcel of land yielding a permanent net income, such as a single piece of downtown real estate in any major city, would be infinite.

A piece of land that is expected to yield a net income year after year, virtually forever, can be sold at a finite price only because of the existence of a positive rate of profit. Assume, for example, that the use of a piece of

land somewhere is expected to be worth just \$1,000 a year, but virtually forever. Even though there is no limit to the total income that this piece of land will eventually yield, it sells at a price that is equivalent to a relatively small number of years' income—perhaps just 10 years' income. If the rate of profit is 10 percent, that is exactly the price for which this piece of land will sell. The \$1,000 annual income from the land will yield a 10 percent rate of profit only if the price of the land is \$10,000 ($\$1,000/\$10,000 = 10$ percent). The existence of a 10 percent annual rate of profit thus leads to the \$1,000 annual income of the land being capitalized at a purchase price of just 10 years' income.

But if the rate of profit were 5 percent instead of 10 percent, that same piece of land, yielding \$1,000 per year forever, would have a price of \$20,000. This is because it takes a \$20,000-capitalized value of the land to make the \$1,000 annual income from the land yield only a 5 percent rate of profit. If, to go further, the rate of profit were 2 percent instead of 5 percent, the capitalized value of the piece of land would be raised to \$50,000, because it takes that much to make a \$1,000 annual income yield only a 2 percent rate of profit. It is not difficult to see that in order for a \$1,000 annual income from the land to constitute a *zero* rate of profit, the capitalized value of the parcel of land would have to be *infinite*.⁹⁹

As the rate of profit falls, therefore, the capitalized value of land in the economic system increases in inverse proportion. And this alone has unlimited potential for raising the value of accumulated assets—and thus of accumulated savings and capital—relative to current income and consumption. It helps to explain why the accumulation of savings and capital relative to income and consumption must always stop far short of the point at which their further accumulation would still be useful. In other words, it helps to explain why capital intensiveness is always *scarce*—why more of it would always be desirable than we can ever actually have. For with the accumulation of the additional savings and capital represented in part by a growing capitalized value of land, people feel free to step up their consumption and, ultimately, not increase the ratio of savings and capital to income and consumption any further.

Because there is always room for additional capital, there is always room for further net investment. But under the conditions of an invariable money, at some point there is no further net investment. As we saw in the last chapter, this is because at that point sufficient net consumption exists to make the rate of profit high enough relative to the marginal productivity of additional capital to make additional net investment no longer worthwhile.¹⁰⁰

The Housing Outlet and Consumer Interest

Saving out of profits and saving out of wages are the only sources of additional capital intensiveness. In both cases, saving is limited by time preference. For wage earners, the ability to earn wages in the future is the main source of provision for the future. Wage earners are motivated to save primarily as the means of providing for periods of inability to earn wages, such as unemployment, illness, accident, and old age. Apart from that, their motivation to save is mainly limited to saving up to buy goods that are too expensive to purchase out of a single pay period, such as appliances, automobiles, and, especially, houses. Most of the savings made by wage earners not only end up ultimately being consumed, as when one dissaves during a period of unemployment or in retirement, or when one buys the consumers' good one has been saving up for, but, as previously explained, they are probably consumed almost immediately upon being set aside, or at least are matched by current consumption. For they are mainly used to finance consumer loans, such as home mortgages and consumer installment loans, and to the extent that they are not, they are largely or entirely offset by loans for such purposes originating in business firms.¹⁰¹

This last—the extent to which saving out of wages does not finance consumption—refers to the savings of wage earners who become businessmen, or whose savings are accumulated within business firms, as in the case of many employee pension plans. As I say, from the perspective of the economic system as a whole, such savings are largely or entirely offset by loans for consumer purposes originating in business firms. Moreover, when such savings become substantial, it is often after the workers in question have begun to succeed as businessmen, in which case, from that point on their saving is saving out of profit income. And in the case of all substantial savings that wage earners accumulate within business firms, a major portion originates in the reinvestment of interest or dividends. Thus, here too the saving is largely saving out of profit income.

For these reasons, the extent of any actual negative net consumption emanating from wage earners is almost certainly not very great, if it exists at all.

It is important to realize that all of the savings wage earners would ever be likely to wish to accumulate relative to their incomes could probably easily be absorbed *just by housing alone*. Even if the average wage earner followed the conservative rule of personal finance of spending no more than a fourth of his income on housing expense, that would probably be sufficient to support an amount of savings invested in housing of five times his annual income. For example, if his income is 100 per year, and he spends 25 on housing, of which 15

represents either the interest he pays on his mortgage or is the equivalent of the profit his landlord earns on him, then at a 3 percent rate of interest or profit, he can have a house or live in an apartment that is worth 500. (If there were sufficient accumulated savings and no increase in the quantity of money or volume of spending, a rate of profit and long-term rate of interest of 3 percent would certainly be achievable.) It follows, moreover, that if the average wage earner accumulates savings of five times his income, those wage earners beginning retirement accumulate savings of ten times their income, balancing the zero accumulated savings of wage earners just starting out. Thus, with far more savings than wage earners are ever likely to seek to accumulate being so easily capable of being employed, there is certainly no problem of the savings of wage earners ever outrunning the uses for such savings just in the field of housing alone.¹⁰²

The Automatic Adjustment of the Rate of Saving to the Need for Capital

Not only does saving out of wages constitute no threat of the supply of savings ever outrunning the uses for savings, but also saving out of profits can never constitute such a threat. This is because in an economy with an invariable money, as soon as the need for additional capital intensiveness diminishes, productive expenditures begin showing up more quickly as costs, with the result that net investment diminishes and the rate of profit falls toward the rate of net consumption. Thus, saving out of profits declines precisely as the need for such savings declines. Note: it is not that a fall in the rate of profit here diminishes the incentive to save; the fall in the rate of profit is part of a process which directly diminishes the *capacity* to save, namely, the excess of profit income over net consumption.

Furthermore, whatever savings businessmen and capitalists might ever wish to make at the expense of a reduction in net consumption can always be easily accommodated. If there were no other way, then simply the use of more expensive materials and the inclusion of more and better components and accessories in the production of products would provide an outlet for such savings and productive expenditure.¹⁰³ But, of course, such an outlet for additional saving and productive expenditure would quickly be followed by an equivalent rise in aggregate costs and fall in profits, which would, once again, equivalently diminish the capacity for further net saving out of profits.¹⁰⁴

The essential point here is that in an economy with an invariable money, saving out of profits, which, in fact, is by far the main form of saving in the economic system, only exists insofar as there is a substantial need for additional capital. In the absence of such a need, produc-

tive expenditure quickly shows up as cost, with the result that profit income immediately falls to the prevailing level of net consumption and, in so doing, simply eliminates net saving and net investment.

In an economy with an invariable money, savings and capital would be accumulated relative to current income up to a point determined by time preference, and would be accumulated no further unless something occurred to make time preference fall. Capital accumulation in physical terms, of course, would go on if the prevailing degree of time preference were sufficiently low and if technological progress took place.

In view of what we shall learn of his views in the next chapter, it may be surprising that Lord Keynes himself alludes to the true state of affairs concerning the relationship between saving and the need for saving under the conditions of an invariable money, but feels free to disregard it merely because he chooses to refer to it in a way that makes its existence seem like only a remote possibility. He writes: “. . . there are no intrinsic reasons for the scarcity of capital. An intrinsic reason for such scarcity . . . would not exist, in the long run, *except in the event of the individual propensity to consume proving to be of such a character that net saving . . . comes to an end before capital has become sufficiently abundant.*”¹⁰⁵

In the peculiar terminology of Keynes, what must be recognized is precisely that—under a system of invariable money—“the individual propensity to consume” is “of such character that net saving . . . comes to an end before capital has become sufficiently abundant.” It does so by virtue of the existence of limitless potential employments for savings and capital in conjunction with the existence of time preference. Under the conditions of an invariable money, long before savings and capital can be accumulated to the point of exhausting the uses for them, which are literally infinite, time preference puts an end to further saving and capital accumulation.

Of course, the conditions of an invariable money do not exist. What exists, even under a 100-percent-reserve gold standard, is an increasing quantity of money. In an economy with an increasing quantity of money and volume of spending, net saving and capital accumulation in monetary terms exist as permanent phenomena. In this context, however, as I showed in the last chapter, they are accompanied by a corresponding *positive addition* to the rate of profit, mainly in the form of an equivalent rate of net investment.¹⁰⁶ In such an economy, as I have shown, the continuing net saving out of profits takes place out of a rate of profit that is elevated by the same cause that necessitates the continuing net saving and continuing capital accumulation in monetary terms, namely, the increase in the quantity of money and volume of spending itself.¹⁰⁷

As we have seen, this net saving and net investment, which takes place as part of a process that increases capital and nominal income in the same proportion, does not represent any rise in the economic system's degree of capital intensiveness in the relative-value sense—that is, it does not represent any rise in the ratio of accumulated savings or capital to consumption, wages, or sales revenues.¹⁰⁸ Capital accumulation here goes forward both in real and in monetary terms without capital rising relative to any of these magnitudes.

Thus, for the reasons explained, in no case is the economic system ever threatened with savings outrun-

ning the profitable uses for savings. The saving of wage earners is no problem, and saving out of profits always takes place in intimate connection with the need for such saving, the capacity for such saving being governed precisely by the strength of the need for it, whether that need is a need to increase the degree of capital intensiveness or, in an economy with an increasing quantity of money, a need to maintain an existing degree of capital intensiveness.

These facts should be kept in mind in appraising the doctrines of Lord Keynes, which I set forth in the next chapter.

Notes

1. See above, pp. 623–626.
2. At the start of *Year 2*, there is no increase in the *total* supply of goods available for sale. At that point, which represents capital accumulation achieved by a rise in the relative demand for capital goods, the 20 percent increase in the supply of capital goods is made possible by an equivalent reduction in the supply of consumers' goods.
3. Indeed, we have already applied this procedure in the critique of the productivity and time preference theories of interest in their traditional forms, by means of introducing the assumption of changes in production into the conceptual framework represented by Figure 16–2. See above, pp. 787–794.
4. The same basic facts appeared in Table 16–5, which was used to illustrate the emergence of net investment and its contribution to the amount of aggregate profit. See above, p. 745.
5. This is because the *IL* of labor and the existing supply of capital goods in each year would then be employed to produce *1.3K* of capital goods and *.7C* of consumers' goods to be available at the start of the next year for each *1K* of capital goods presently existing. Thus, with *1.3K* of capital goods produced for every *1K* of capital goods productively consumed, the supply of capital goods and total productive ability would grow in the ratio of 1.3:1. It should be understood that the outputs of *1.3K* and *.7C* for every *1K* of capital goods productively consumed are inferred by multiplying *.65 x 2K* and *.35 x 2C*. The multiplicands *2K* and *2C*, of course, are the outputs of capital goods and consumers' goods that would result from the employment of 100 percent of the *IL* of labor and 100 percent of any existing *1K* of capital goods in the production of capital goods or, alternatively, in the production of consumers' goods. Of course, there are conditions in which the rise in the relative demand for and production of capital goods would be followed by an acceleration in the rate of capital accumulation and economic progress that represented a deceleration in the rate of acceleration. On this point, see above, pp. 628–629.
6. See above, p. 630.
7. For a fuller account of the destructive influence of this view, see above, p. 709.
8. See above, pp. 674–699.
9. A rise in the demand for capital goods relative to the demand for consumers' goods could take place without a fall in net

- consumption only by virtue of the demand for capital goods rising at the expense of the demand for labor.
10. See above, p. 573.
11. Essentially the same conclusions, of course, were reached back in Chapter 13. However, there the assumption of vertical integration precluded discussion of the falling prices of capital goods. See above, pp. 569–570.
12. See above, pp. 758–759.
13. A similar formulation appeared back on p. 570. As pointed out in the note before last, however, the assumption of vertical integration that was made at the time, prevented inclusion of capital goods in the analysis.
14. See above, pp. 573–580.
15. On this last point, see above, pp. 575–576.
16. See above, pp. 557–558.
17. The nature of the monetary component in the rate of profit and its relationship to net investment is explained above, on pp. 762–774. See in particular pp. 768–771.
18. David Ricardo, *Principles of Political Economy and Taxation*, 3d ed. (London, 1821), chap. 7; reprinted as vol. 1 of *The Works and Correspondence of David Ricardo*, ed. Piero Sraffa (Cambridge: Cambridge University Press, 1962), p. 133. This passage was quoted above, on p. 495, in connection with showing the actual meaning Ricardo attached to “a fall in wages.” Subsequent page references to the Sraffa edition appear in brackets.
19. *Ibid.*, chap. 20 [pp. 278–279]. Inserts added.
20. *Ibid.*, chap. 5 [p. 95].
21. On this point, see below, p. 824. See also above, pp. 631–632.
22. This, of course, is apart from a transition phase, during which a fall in the rate of net consumption occurs as the precondition of increasing the relative demand for capital goods and thus their relative production, and thereby getting the process of increasing production underway. On this subject, be sure to see above, pp. 817–818.
23. This is true irrespective of the extent of saving by wage earners and of the extent to which their saving serves to raise productive expenditure. See above, pp. 750–754 and 759–762. See also above, pp. 778–787, and below, pp. 856–859.
24. Concerning this fact, see above, pp. 817–818.

25. Concerning the effects of a more abundant supply of savings and credit on the demand for money for holding and thus on the velocity of circulation of money, see above, p. 518.
26. See above, pp. 817–818. See also above, pp. 762–767.
27. See below, pp. 837–838.
28. It is implicit in this example that all of the capital goods and labor in existence in any base year are always ultimately, directly or indirectly, devoted to the production of consumers' goods in their entirety. For application of this fact to the fallacy of underconsumptionism, see below, pp. 847–851.
29. The writings of Murray Rothbard present a clear instance of error on this subject and on the closely related subject of whether or not capital accumulation implies a falling rate of profit. Rothbard simply does not see how previous capital accumulation can serve as the basis for subsequent capital accumulation. Nor does he understand the role in capital accumulation of technological progress and anything else that increases the general ability to produce. Cf. Murray N. Rothbard, *Man, Economy, and State*, 2 vols. (Princeton, N. J.: D. Van Nostrand, Inc.: 1962), 2:470–496.
30. On the subject of past production serving the present, and present production serving the future, see Eugen von Böhm-Bawerk, *Capital and Interest*, 3 vols., trans. George D. Huncke and Hans F. Sennholz (South Holland, Ill.: Libertarian Press, 1959), 2:88.
31. See above, pp. 631–632.
32. See Ludwig von Mises, *Human Action*, 3d ed. rev. (Chicago: Henry Regnery Co., 1966), pp. 541–545.
33. It should be recalled that it was also previously established that the anticipation of falling prices caused by increased production does not bring about an increase in the demand for money for holding in order to take advantage of lower prices in the future. Thus it is also not deflationary by that route. See above, pp. 574–576.
34. See above, pp. 813–818 and 574.
35. See above, pp. 817–818.
36. On the implications of these facts for the case for a 100-percent-reserve gold standard or gold-and-silver standard, see below, pp. 954–959.
37. See above, p. 176.
38. Indeed, in my own intellectual development, it was the grasp of the implications present in an intellectual construction essentially similar to Figure 17–1 that led me to the development of the productivity theory of wages and to most of the other major propositions of the second half of this book.
39. It should be kept in mind that profit is taken as gross of interest, and that the analysis applies equally to interest income and the rate of interest.
40. See above, p. 740 and pp. 741–743. See also the quotation from von Mises concerning the effect of eliminating the capitalist's role as receiver of interest causing its replacement by the capitalist's role as consumer of capital, above, on p. 302.
41. In support of this pattern of outcome, see above, p. 740.
42. See above, pp. 712–714.
43. In this case, there is a rise in nominal national income to the extent that the economy-wide demand for labor is increased. To this extent, of course, the case at hand is also one demonstrating an inverse relationship between national income and prosperity. See above, pp. 648–650. for a detailed explanation of the negative effects for prosperity.
44. See above, pp. 762–771.
45. To some extent, private consumption expenditure that would have been financed by borrowing, is also reduced, such as home buying and purchases dependent on consumer installment credit.
46. In the case of taxation, of course, the rise in the rate of profit is on a pretax basis, while in the case of budget deficits, it is on an aftertax basis.
47. See below, pp. 930–937.
48. As I have shown, just such a policy has been pursued in Sweden, the model country of today's "liberals." See above, p. 310.
49. A program for the abolition of the welfare state and all government interference in the economic system is presented in the concluding chapter of this book.
50. Concerning the fact that foreign investment entails an excess of exports over imports in the country or countries providing the investment and a corresponding excess of imports over exports in the country or countries receiving the investment, see above, pp. 529–531.
51. See above, pp. 531–532.
52. If the two countries use different moneys, then with the same rates of increase in the money supply of the two countries, the foreign exchange value of the currency of the more rapidly progressing country will appreciate relative to that of the less rapidly progressing country. The relative appreciation will be all the greater to the extent that the money supply of the less rapidly progressing country increases at a more rapid rate than that of the more rapidly progressing country.
53. The replacement of social security by private saving would promote investment even though the savings of wage earners are used largely to finance consumption expenditures, such as housing purchases. This is because the availability of these savings to finance such purchases would correspondingly reduce the diversion of savings from business investment that must presently occur in order to finance such purchases.
54. See above, pp. 737–739.
55. See above, pp. 622–639, in particular pp. 634–636.
56. Strictly speaking, it would be the establishment of laissez-faire capitalism for the very first time. For an indication of the significant departures from laissez-faire capitalism even in the nineteenth century, see above, p. 28.
57. See above, pp. 830–831. See also above, pp. 308–310.
58. See above, p. 278. See also above, pp. 639–641.
59. See above, pp. 758–759.
60. For example, see above, *ibid.*
61. See above, pp. 739–741, 753–754, and 759–762.
62. It should go without saying that if the equilibrium capital-intensiveness in the relative-value sense is sufficiently high, the degree of capital intensiveness in the *physical sense* of the ratio of capital goods to the supply of labor can go on rising indefinitely, on the basis of technological progress, whose implementation is encouraged by the sufficiently high degree of capital intensiveness in the relative-value sense.
63. Of course, increases in the quantity of money and volume of spending operate to an important extent directly to increase the nominal value of assets, both capital assets and consumer assets, especially in the form of land. These increases must be taken into account in calculating the percentage of income that

must be saved in order to maintain the ratio of accumulated savings to current income. Their influence is obviously to lessen the percentage of ordinary income—that is, income other than asset gains—that needs to be saved.

64. On the economic degree of capitalism, see above, pp. 632–634.

65. See above, pp. 631–632. See also above, p. 824.

66. The same point applies, of course, to the degree of capital intensiveness in the relative-value sense. It too operates as force to acceleration.

67. On these subjects, see above, p. 709.

68. See above, pp. 691–694.

69. To the extent that the cash holdings were outside of business firms, the rate of profit on the whole of the capital invested in business firms, including the cash holdings of business firms, would be correspondingly increased.

70. On the Keynesian doctrines, see below, pp. 863–894. On the Keynesian doctrine of the too-low rate of profit in particular, see below, pp. 868–876. On the liquidity-preference doctrine in particular, see pp. 885–887. See also pp. 891–892. The last reference explains why I claim that the Keynesians' fears of too low a rate of profit are pretended.

71. Concerning the "Pigou effect" and its inherent weakness, see below, pp. 865–866.

72. For an account of the government's role in causing financial contractions and depressions, see above, pp. 513–516 and 519–526. See also below, pp. 938–941.

73. For elaboration of this point, see above, pp. 750–754 and 759–762. See also, below, pp. 856–859.

74. For a critique of Keynesian claims to the contrary, see below, pp. 885–887.

75. For a textbook exposition of the investment-opportunity doctrine, see Paul Samuelson and William Nordhaus, *Economics*, 13th ed. (New York: McGraw Hill Book Company, 1989), pp. 720–725.

76. See above, pp. 787–792.

77. As I previously pointed out, as far as it corresponds to net investment, the magnitude of profit is in part also attributable to the difference between the supply of products and the supply of factors of production previously purchased. See above, p. 796.

78. See above, pp. 556–558.

79. As we have seen the reduction in unit costs it achieves takes place prior to the fall in selling prices. See above, pp. 807–817.

80. On all of these points, see above, pp. 556–558.

81. The degree of capital intensiveness should, of course, also be included in the list of actual causes of capital accumulation and increases in production. I omit it here, merely for the sake of economy of expression.

82. Strictly speaking, it is a consequence of the by-product, namely, the increase in the quantity of money and volume of spending. Under a system of fiat money, the status of net saving is even less than that. Then it is a consequence not even of a by-product of capital accumulation and rising production but of a mere accompaniment of these phenomena, that is, of the accompaniment constituted by the increase in the quantity of fiat money.

83. On the Platonic-Heraclitean view of entities, see above, pp. 674–689.

84. Quoted in John Maynard Keynes, *The General Theory of Employment, Interest, and Money* (New York: Harcourt, Brace, 1936), p. 367. Along the same lines, see the quotation from Spence by James Mill in James Mill, *Commerce Defended* (London, 1808), chap. 6; reprinted in *Selected Economic Writings of James Mill*, ed. Donald Winch (Chicago: University of Chicago Press, 1966), p. 131. See also the underconsumptionist writings of W. T. Foster and W. Catchings: *Money*, Publications of the Pollak Foundation for Economic Research, no. 2 (Boston and New York: Houghton Mifflin, 1923); *Profits*, Publications of the Pollak Foundation for Economic Research, no. 8 (Boston and New York: Houghton Mifflin, 1925); *Business Without A Buyer*, Publications of the Pollak Foundation for Economic Research, no. 10 (Boston and New York: Houghton Mifflin, 1928).

85. See above, pp. 56–58. See also above, pp. 556–557.

86. The pattern of my resolution of the underconsumptionists' paradox in what follows has been inspired largely by the writings of F. A. Hayek. See in particular his essay "The 'Paradox' of Saving" in his book *Profits, Interest and Investment* (London: Routledge and Kegan Paul, 1950). See also his treatment of the structure of production in *Prices and Production*, 2d ed. (London: George Routledge, 1935), pp. 29–64. But equal or even greater credit should go to James Mill. See the latter's *Commerce Defended*, chap. 6; reprinted in *Selected Economic Writings of James Mill*, pp. 127–133.

87. Concerning double counting, see above, pp. 674–682.

88. Cf. Carl Menger, *Principles of Economics*, trans. and ed. by James Dingwall and Bert F. Hoselitz (Glencoe, Ill.: The Free Press, 1950), pp. 55–67.

89. On this point, see Eugen von Böhm-Bawerk, *Capital and Interest*, 2:77–118, for a discussion of how current production serves the future and is served by the production of the past.

90. In terms of the format of Table 17–2, these expenditures would represent the addition of further columns to the right of those in the present Table 17–2. Thus, there would be a column headed D_{K5} , just to the right of the present rightmost column, which is headed D_{K4} . The outlays of 65.54 plus 8.19 would appear in this column and would serve in the production of capital goods that would be sold in the next year, under the column heading D_{K4} , for 81.92. Five columns further to the right would appear a column headed D_{K10} . In this column would appear the outlays 21.47 and 2.68, which would serve in the production of capital goods that would be sold in the next year under the column heading D_{K9} . A series of downward and leftward sloping arrows would connect these outlays with the sale of capital goods five years later, under the column heading D_{K5} , and, five years after that, with sale of consumers' goods.

91. It is possible that if he takes the trouble to check all of the arithmetic involved in the construction of Table 17–3, the reader will arrive at slightly different totals as the result of differences in rounding. My procedure has been to calculate the amounts in columns three and four year by year and then to derive from them both their totals and the respective amounts shown in column five.

92. For Figures 17–2 and 17–3, see above, pp. 821 and 823.

93. See above, pp. 824–824.

94. See Böhm-Bawerk, *Capital and Interest*, 2:79–88, for an alternative approach to the measurement of the average period

of production.

95. On the equality of prices with sums of past wages and profits, see above, p. 201. See also above, pp. 639–641 and 647.

96. Note that in the case of an infinite rate of profit accompanied by an infinite ratio of the demand for consumers' goods to the demand for labor, namely, the case of Adam Smith's "early and rude state of society" and Marx's "C–M–C," the average period of production is extremely short, despite the fact that it appears to be mathematically undefined in the present discussion. This is because the case contains no demand for capital goods and no accumulated capital. In such conditions, production is of the hand-to-mouth variety.

97. See above, pp. 759–762.

98. For a description of the virtually limitless quantities in which additional capital would be useful in reducing costs and/or improving the quality of products, see above, pp. 56–58.

99. Cf. Ludwig von Mises, *Human Action*, p. 526.

100. See above, pp. 758–762.

101. See above, p. 735.

102. Of course, it should be recalled that the payment of interest on consumer loans, such as home mortgages, represents a further source of net consumption and thus of aggregate profit and interest. See above, p. 753.

103. Along these lines, see above, pp. 854–856.

104. The use of funds released from net consumption for such purposes, of course, would occur only if there were no greater need for additional capital, such as would require the employment of the funds spared from net consumption in the making of productive expenditures that were more remote from showing up as costs.

105. John Maynard Keynes, *The General Theory of Employment, Interest, and Money* (New York: Harcourt, Brace, 1936) p. 376. Italics supplied.

106. See above, pp. 762–774, especially p. 768.

107. See above, the preceding note. See also above, pp. 825–826 and 836–840.

108. See above, pp. 775–776.

CHAPTER 18

KEYNESIANISM: A CRITIQUE

In previous chapters, I have criticized various major aspects of Keynesianism, notably the Keynesian approach to aggregate economic accounting, its negative view of saving, and the multiplier doctrine in its various forms.¹ Very significantly, I have also shown that insofar as people might choose to hold accumulated savings in the form of cash rather than income-producing assets, the effect would be to raise the rate of return on the income producing assets, thereby automatically limiting any possible preference people might have for holding savings in the form of cash and rendering impossible the limitless rise in “liquidity preference”—viz., cash hoarding—alleged by the Keynesians to exist in response to too low a rate of profit.² Of course, I also showed how the determinants of the rate of profit, along with the enormous abundance of profitable investment opportunities for additional capital, preclude any actual need for people in modern conditions to attempt to accumulate a major portion of their savings in the form of cash in the first place. I demonstrated that the profitability of investment, and thus the superiority of investing rather than holding cash, is guaranteed by the very nature of the forces that determine the rate of profit, including the existence of veritable “springs” to profitability.³

In addition, I showed that what leads to efforts to hold a greater portion of accumulated savings in the form of cash is not any lack of investment opportunities in the economic system as it is basically constituted, but undue increases in the quantity of money, which almost always take place, ironically enough, precisely in the conviction that spending needs to be stimulated. The result, I show-

ed, is that cash holdings are driven down relative to the volume of spending and lending in the economic system—viz., business becomes illiquid—and the stage is thereby set for a financial contraction once the stimulus of the additional quantity of money comes to an end and the normal demand for money for holding reasserts itself.⁴

My demonstration that the rate of interest is not the “price of money” and cannot be permanently reduced, let alone eliminated, by virtue of the increase in the quantity of money, can also be counted as a criticism of Keynesianism.⁵ This is because Keynesianism ardently embraces this doctrine and makes it central to its views on “monetary policy.”⁶

Up to now, I have dealt with Keynesianism either merely by implication or on the fly, so to speak. It is difficult to do otherwise, because conceptually Keynesianism is a form of amorphous sludge, oozing its way through any possible cracks or chinks in the intellectual armor of a capitalist economy and thereby undermining as far as possible the intellectual foundations of such an economy. Before turning full face to Keynesianism, it has been necessary to set right a number of major theoretical issues that are wider than Keynesianism. Yet, from time to time, I have felt morally obliged to deal explicitly with various Keynesian positions at the earliest opportunity, just as soon as my own theoretical position was in place.

Here I turn to an exposition of Keynesianism in its best organized, strongest form, preparatory to slaying the dragon one more time, with a critique of all of the doctrine’s remaining essential claims whether in the realm of economic theory or in the realm of economic policy.

This is the variant that goes under the name the *IS-LM* analysis.

I believe that my exposition of this analysis is far more compact and much clearer than those to be found in the very best of the Keynesian textbooks. At the same time, I am confident that any honest Keynesian will agree with the substance of my exposition. I consider the superiority of my exposition to be based on the fact that I have reversed the usual order of development of the doctrine. I begin with the Keynesian view of aggregate demand, whose significance can be understood immediately, and then proceed to explain the underlying doctrines on which it is based. The usual procedure is to devote chapter after chapter to subjects apparently leading nowhere, such as the “consumption and saving functions,” the various “multipliers,” the “marginal efficiency of capital schedule,” “liquidity preference,” and so on, and then at the very end pull all the elements together into the central argument concerning aggregate demand. By that time, as I will show, the reader has forgotten the essential questions and is no longer in a position to see that the wool is being pulled over his eyes. In contrast, my procedure keeps all of the elements in sharpest focus and never allows sight of the essential questions to be lost.

1. The Essential Claims of Keynesianism

Prior to the publication of Keynes’s book *The General Theory of Employment, Interest, and Money* in 1936, economists had accepted the proposition that unemployment can be eliminated by a fall in wage rates.⁷ This was an intellectually uncomfortable position for most economists to be in, because its obvious implication is that, in order to prevent or eliminate unemployment, the government should abstain from interfering with the height of wage rates—i.e., should not enact pronoun legislation, minimum-wage laws, or in any other way coerce or pressure employers into paying wages higher than those which a free market would establish.

This position, of course, was in direct conflict with the Marxian exploitation theory, which exerted a powerful influence probably over the majority even of the economics profession and certainly over the overwhelming majority of intellectuals in all other fields. For according to the exploitation theory, a free market in labor means subsistence wages, unbearably long hours of work, and inhuman working conditions. Thus, acceptance of the doctrine that a free market in labor can eliminate unemployment by means of a fall in wages placed economists in a position in which they appeared to be virtual enemies of mankind and in which virtually they alone stood in opposition to what was (and by many still is) regarded as the only possible path of social progress—namely, ever-

growing government interference and ultimately, if not immediately, socialism.

In this intellectual environment, Keynes appeared on the scene. His entire system can be summarized in a single sentence: *A free market in labor and fall in wage rates is incapable of eliminating unemployment; mass unemployment is an inescapable feature of a capitalist economic system in modern conditions.* Thus, Keynesianism held, it is pointless to fight for a free market in labor. Because even if it were achieved, it would be to no avail. On the contrary, the only solution is “fiscal policy”—by which, in essence, is meant that the government must adopt a policy of budget deficits.

In this way, Keynes’s ideas filled what perhaps the majority of economists experienced as a vital need—it gave them a way out of conflict with the rest of the intellectual world and with a good portion of their own convictions. For if Keynes were right, economists need not oppose labor legislation. Indeed, they could join in the calls for expanded government intervention. This is because Keynes also gave them arguments designed to show that the more the government spends for any purpose—even for the least valuable programs imaginable, even for pyramid building—the more prosperous must the economic system become.⁸

If one considers the implications of such ideas as that pyramid building and budget deficits are economically beneficial, it becomes obvious that Keynesianism is the enemy both of common sense and the love of liberty (viz., the freedom from excessive government, which excess is fostered by the policy of budget deficits). Keynesianism is also incompatible with such fundamental economic truths as the quantity theory of money. And, if it is not already apparent, we shall see, too, how it is actually nothing more than a species of consumptionism.

The incompatibility of Keynesianism with the quantity theory of money requires some comment. Keynesianism implies that even though the quantity of money remains the same, the volume of spending in the economic system falls without limit as wages and prices fall, and thus that no connection whatever exists between the quantity of money and volume of spending. It implies this because if spending does not fall in full proportion to the fall in wage rates and prices, thus totally obliterating the connection between the volume of spending and the quantity of money, the fall in wage rates and prices must result in larger quantities of goods and labor being sold, and thus, at some point, in the elimination of unemployment. If, as the quantity theory of money in fact implies, the volume of spending tends to remain unchanged in the face of a given quantity of money, then, of course, reductions in wage rates and prices must put an end to unemployment in short order. And, indeed, as we saw in the discussion

of unemployment, there is actually good reason for believing that when wage rates and prices fall to their new equilibrium level following a financial contraction, total spending in the economic system will actually increase, since it first declines in part as the result of the postponement of investments precisely to that time.⁹

The incompatibility of Keynesianism with so much of established sound economic doctrine and with the traditional Anglo-Saxon acceptance of the political philosophy of limited government, and, no less, its open flaunting of the absurd and paradoxical as newly discovered truths, deservedly aroused great opposition. Unfortunately, the critics were not able to answer the Keynesian sophistries decisively.

The reason was that in the two generations preceding the appearance of Keynes, much of the foundations of sound economics had quietly been lost, without anyone even being aware of the loss. The loss took place starting in the 1870s, in the abandonment of British classical economics in favor of the newer neoclassical economics. As explained in Chapter 11, the cause of this development was the fact that classical economics, with its labor theory of value, appeared to lay the groundwork for Marxism. Instead of eliminating the particular, localized errors of classical economics which did provide support for Marxism and then integrating the new doctrine of marginal utility propounded by neoclassical economics with the essential substance of classical economics that remained, virtually the whole theoretical body of knowledge constituted by classical economics was abandoned. What then remained were largely just out-of-context, memorized conclusions that in the absence of the necessary theoretical foundations could no longer be supported. Thus, when Keynes came along, it was only necessary for him to overturn such out-of-context, intellectually severed conclusions, not serious, living convictions. The state of underlying intellectual decay that had set in long before Keynes appeared is clearly indicated in a passage written by J. A. Hobson as far back as 1889, a passage which Keynes quotes approvingly:

Saving enriches and spending impoverishes the community along with the individual, and it may be generally defined as an assertion that the effective love of money is the root of all economic good. Not merely does it enrich the thrifty individual himself, but it raises wages, gives work to the unemployed, and scatters blessings on every side. From the daily papers to the latest economic treatise, from the pulpit to the House of Commons, this conclusion is reiterated and re-stated till it appears positively impious to question it. Yet the educated world, supported by the majority of economic thinkers, up to the publication of Ricardo's work strenuously denied this doctrine, and its ultimate acceptance was exclusively due to their inability to meet the now exploded wages-fund doctrine. That the conclusion should have survived the argument on which it logi-

cally stood, can be explained on no other hypothesis than the commanding authority of the great men who asserted it. Economic critics have ventured to attack the theory in detail, but they have shrunk appalled from touching its main conclusions.¹⁰

The wages-fund doctrine referred to by Hobson, is, of course, the doctrine that holds—correctly—that the demand for labor is separate and distinct from the demand for consumers' goods, and is made out of saving and productive expenditure, not consumption expenditure. As I showed in Chapter 14, it was never actually refuted. The essential criticism raised against it was merely that changes in wage rates might be accompanied by changes in total payrolls coming at the expense of other portions of productive expenditure or at the expense of net consumption.¹¹ I have already explained very well how to analyze such changes in total payrolls, namely, that little or nothing can be obtained at the expense of net consumption and that what can be obtained at the expense of other parts of productive expenditure is against the long-run interests of the wage earners.¹² The possible variation of total payrolls in no way affects the essential fact that wages are paid out of saving and productive expenditure and in real terms depend on the economic degree of capitalism and productivity of labor. The wages-fund doctrine was not overthrown; it was simply left undefended. It was left undefended because it was an integral part of classical economics, which had ceased to be seriously valued and studied. As I have shown, there was—and is—no justifiable basis for abandoning the doctrine.

What Hobson was absolutely correct in pointing out, however, and which is my reason for quoting him, is that the abandonment of the wages-fund doctrine, and other such essential doctrines of classical economics, did have the effect of withdrawing the foundation for conclusions that could otherwise not be supported.

Neo-Keynesianism

In response to some relatively mild criticism levied by a colleague of Keynes at Cambridge University, A. C. Pigou, Keynesianism was succeeded by "neo-Keynesianism." According to this variant, which concedes the substance of Pigou's criticism, a fall in wage rates might, conceivably, be capable of eliminating unemployment, but the fall would have to be enormously out of proportion to any additional employment achieved. The clear implication is that in the process virtually every debtor would be bankrupted, because the grossly disproportionate drop in wage rates and prices implies correspondingly large reductions in aggregate spending and revenues and thus in the ability to repay debts. For example, if to eliminate an unemployment rate of 10 percent, wage rates and prices had to fall by 90 percent, the volume of

spending in the economic system would equal one-tenth the price-and-wage level times ten-ninths the output and employment. Thus, total spending would be reduced to one ninth of its former height, or by 89 percent.

And, even if people were willing to allow such a thing to transpire, the further argument is ready at hand that a necessary condition of prices being able to fall would be the adoption of a radical antitrust policy, or a program of widespread nationalization of industry. These measures would allegedly be necessary to establish “price competition.” Big business, left to its own devices, it is held, is “oligopolistic” and practices “administered pricing”—i.e., won’t reduce prices. Thus, either it must be broken up into large numbers of small competitors, to approximate the conditions of “pure and perfect competition,” or the government must take it over and set prices.¹³ Thus, neo-Keynesianism, no less than Keynesianism, holds that a free market is incompatible with full employment. The only difference is that while Keynesianism claims that a free market in labor cannot establish full employment, neo-Keynesianism claims that a free market in products cannot establish full employment, for the free market in products allegedly results in “oligopoly” and the refusal to cut prices. Thus, according to both variants, a free economy must be accompanied by mass unemployment.

Much of the substance of neo-Keynesianism is clearly stated by Joseph P. McKenna, a supporter of Keynes, in his relatively readable textbook *Aggregate Economic Analysis*:

Keynes’s conclusions were unacceptable to two groups. The first group objected because his analysis made government intervention or continued depression the only two possible alternatives. Many members of this group opposed government intervention in principle and therefore rejected this choice as undesirable.

The second group, the supporters of classical analysis, opposed Keynes’s conclusions on logical rather than political grounds. To them, it seemed impossible that workers could not find jobs by cutting their wages sufficiently. Among this group was A. C. Pigou, who discussed the question in his article “The Classical Stationary State.” He observed that price changes would alter the consumption function. . . . A decline in prices tends to raise the value of money assets and, therefore, to shift the consumption function upward. . . .

This result satisfied Pigou. He had proved that it was always possible to obtain full employment if wages and prices fell sufficiently. As a logical proposition this conclusion was almost indisputable, and Pigou claimed nothing more than logic. (Pigou himself made it clear though that, as matter of policy, he preferred to increase demand through fiscal policy.) Strangely enough, this result also satisfied the political opponents of Keynes, who could now blame unemployment on the unwillingness of workers to accept

lower wages, for Pigou had shown that there exists *some* level of wages that would be compatible with full employment. The important practical question was an empirical one: Just how elastic is the aggregate demand curve? If the elasticity is very high, a modest change in price might produce the desired income level. If the elasticity is low, the price level that is compatible with full employment might require such a large change that the process of reaching it would be hopelessly disruptive. (Imagine what would happen if it were necessary to lower the price level to one-tenth its present level.)

The question of how much prices must change to produce a given level of income [viz., real income and employment] cannot be answered by any purely theoretical analysis. Only statistical study, concerned with the size of consumer assets and debts and the effects of these upon consumption, could offer even a tentative hypothesis. The usual conclusion is that the aggregate demand curve is inelastic, so that very large changes in prices would be required for moderate changes in income. Nevertheless, the controversy is not yet settled, and further study continues.¹⁴

The reason for such negative conclusions about the extent of the fall in wage rates and prices necessary to achieve full employment is that Pigou and the other neo-Keynesians are trapped in the Keynesian intellectual framework. The only mechanism they can imagine by which a fall in wage rates and prices can increase the quantity of goods and labor demanded is by virtue of its effect in increasing the buying power of the stock of money. Once in possession of a stock of money of larger real purchasing power, people will be willing to consume more, and this will create additional employment. Obviously the doctrine views an additional demand for consumers’ goods as equivalent to an additional demand for labor.

Actually, Pigou’s doctrine is even weaker than the Keynesians themselves recognize. For if the money of the economic system rests on a fractional reserve, and if it were the case that there must be some significant drop in total spending accompanying the fall in wage rates and prices, then there would be substantial business failures, which would result in substantial bank failures and in a reduction in the quantity of money. In such a case, the “Pigou effect” would be reduced to depending on the ability of a fall in wage rates and prices to raise the purchasing power not of a fixed stock of money (which would not be fixed, but falling) but of a much more limited fixed *monetary base*.¹⁵

Obviously the answer to Keynes concerning the effect of a fall in wage rates must be far more powerful than the answer provided by Pigou. After I have set forth the essential elements of Keynes’s doctrine, I will provide such an answer.

In its most recent incarnation, neo-Keynesianism has

abandoned the claim that the problem is an inelastic aggregate demand curve, or, indeed, has anything fundamentally to do with a problem on the side of demand. It has given up the whole substance of the Keynesian position and retreated to the claim that wages and prices are somehow inflexible in the downward direction and that this inflexibility is what necessitates government intervention to alleviate unemployment—as though the inflexibility (and the periodic reductions in aggregate monetary demand that exacerbate it) were not itself the result of government intervention. In the most brazen misrepresentation of the views both of the classical economists and of Keynes, Samuelson and Nordhaus declare in the most recent edition of their textbook:

The basic difference between classical and Keynesian approaches can be found in differing views about the behavior of aggregate *supply*.^[!] Keynesian economists believe that prices and wages adjust slowly, so any equilibrating forces may take many years or even decades to operate. The classical approach holds that prices and wages are flexible, so the economy moves to its long-run equilibrium very quickly. . . . While the classical economists were preaching that persistent unemployment was impossible, economists of the 1930s could hardly ignore the vast army of unemployed workers Keynes emphasized that because wages and prices are inflexible, there is no economic mechanism to restore full employment and ensure that the economy produces its potential. . . . In the Keynesian model, aggregate supply slopes upward, implying that output will increase with higher aggregate demand as long as there are unused resources.¹⁶

Thus, what currently remains of the Keynesian position is merely an obstinate refusal to challenge the government intervention that is responsible for mass unemployment, and an insistence that the problem of unemployment be dealt with by means of still more government intervention.

In view of the virtually total intellectual capitulation of today's neo-Keynesians, it may be asked why I believe it is necessary to engage in an extensive critique of Keynes's actual doctrine when his supporters themselves have apparently abandoned it and proceed as though he never even held it. My reason is—precisely as the passages quoted above indicate—that the world abounds with prominent intellectuals who do not take ideas very seriously—who adopt them and then discard them on the basis of no more genuine intellectual conviction than stands behind a change in such fashions as the height of women's hemlines or the width of men's neckties. What has been casually discarded for the present can just as easily be picked up again in the future. My purpose in what follows is to provide intellectuals who do take ideas seriously with the means of quashing any possible future resurrection of Keynesianism.

2. The Unemployment-Equilibrium Doctrine and Its Basis: The *IS* Curve and Its Elements

The Keynesian doctrine that a free economy cannot escape from mass unemployment, that a fall in wage rates and prices is useless, because it is accompanied by a corresponding fall in the aggregate monetary demands for consumers' goods and labor, is known as the doctrine of *the unemployment equilibrium*. This doctrine is a species of out-and-out consumptionism, as its diagrammatic exposition (provided by the Keynesian textbooks themselves) clearly demonstrates. For what is presented as the Keynesian aggregate demand curve in Figure 18–1 is nothing other than the very same aggregate demand curve we examined earlier, in Chapter 13, as representing the views of the consumptionists.¹⁷ All that is different is the description of the horizontal axis as representing employment as well as output, and, following the customary, Keynesian practice, the use of the letter *Y* to denote output.

The presentation of the Keynesian aggregate demand curve *DD* as absolutely inelastic—as a vertical line—and the belief that as wage rates and prices fall, the aggregate monetary demands, i.e., the respective volumes of spending, fall in proportion, are mutual corollaries. If people are prepared to buy just so much in physical terms and no more, then any fall in the price of what they buy must be accompanied by a proportional fall in the overall amount of money they spend in buying it. By the same token, if as wage rates and prices fall, people reduce the amount of their monetary demand in proportion, then they are capable of buying no more at the lower wage rates and prices than they bought at the higher wage rates and prices.

The strictly limited quantity of output and employment that is depicted by *DD* is allegedly all that a free market is capable of absorbing in a given period of time, and thus all that it is allegedly capable of demanding. Just as in the case of consumptionism, unemployment supposedly results because (and exists to the degree that) the economic system is capable of producing more at the point of full employment than corresponds to the allegedly fixed aggregate quantity of goods and labor demanded. In the diagram, output at the point of full employment (denoted by *Y_f*) is indicated by the vertical line *SS*, which is drawn to the right of *DD*. In other words, Keynesianism in essence is really nothing more than the overproduction doctrine. It simply adds some peculiar twists and turns.

These twists and turns concern how Keynesianism arrives at the notion of a fixed aggregate quantity of goods and labor demanded. One route is the widely held belief, fostered by labor unions, that because a cut in

wage rates reduces the ability of the individual wage earner to spend money for consumers' goods, it correspondingly reduces overall spending for consumers' goods in the economic system. This is an elementary fallacy. It does not see that the reduction in wage rates makes possible the employment of correspondingly more wage earners, with the result that the total amount of spending—the monetary demand—for consumers' goods does not fall. The basic result is the existence of the same amount of monetary demand both for labor and for consumers' goods, but because wage rates and prices are lower, the same respective monetary demands employ more labor and buy more consumers' goods.¹⁸

Of course, the demand for labor and the wage earners' demand for consumers' goods are not the only relevant monetary demands in the economic system. There is also the demand for capital goods and the demand for consumers' goods on the part of businessmen and capitalists, i.e., net consumption. It is entirely possible that under an invariable money, a fall in wage rates would be accompanied by some change in the demand for labor accompanied by an equal and opposite change in one of these other elements, especially in the demand for capital goods. But even if this entailed some fall in the aggregate monetary demand for labor, over and against this is the fact that in the context of the elimination of mass unemployment the fall in wage rates to their new equilibrium level almost certainly results in a rise in spending of virtually all kinds, including the demand for labor. This is because in a situation of mass unemployment the fall in wage rates brings out the investment expenditures which had been postponed, awaiting their fall. Thus, in actuality, the fall in wage rates to their new equilibrium is accompanied by a rise in the aggregate monetary

demands for labor and for goods, both consumers' goods and capital goods.¹⁹

Despite the widespread impression to the contrary, the fallacy that lower wage rates are the cause of proportionately less spending, is not the major argument that Keynesianism advances in support of a vertical aggregate demand curve—that is, in support of the notion that the aggregate quantity demanded is fixed. The actual doctrine it relies on is the so-called *IS* curve and the relationships from which it is derived. An *IS* curve appears in Figure 18–2.²⁰

The *IS* curve is the relationship between the “marginal efficiency of capital” (viz., the rate of profit and interest), on the one side, and the volume of output and employment, on the other, for equilibria of investment and saving. (The meaning of this definition will become clearer as we proceed.) The *IS* curve purports to show that as output and employment expand, as measured along the horizontal axis, the rate of return on capital falls, as measured along the vertical axis. (Output is represented by *Y* and the rate of return is represented by *r*.) The Keynesians claim that at the point of full employment and its corresponding output, namely Y_f , the rate of return would either be negative or, if not negative, at least unacceptably low—below 2 percent is the usual estimate of what is unacceptably low.²¹ *This alleged insufficiency of the rate of return that would exist if full employment were achieved is supposed to be the reason that full employment cannot exist, or if it did exist, could not be maintained.*

Observe that in Figure 18–2 full employment and the output it results in are alleged to be accompanied by a rate of return on capital of zero. The specific assumption of a zero rate of return is not necessary. Any rate of return

Figure 18–1

The Keynesian Aggregate Demand Curve and the “Unemployment Equilibrium”

Figure 18–2
The *IS* Curve

on capital of less than 2 percent is held to be unacceptably low. At any such rate of return, the Keynesians argue, businessmen and investors will prefer to hoard cash rather than to invest. Thus, if full employment requires any rate of return below 2 percent, the existence of full employment is allegedly impossible, at least as a lasting phenomenon. And this, according to the Keynesians, is exactly what it does require and is why its existence is allegedly impossible. Full employment cannot exist under the conditions of modern capitalism, say the Keynesians, because its existence requires a rate of return on capital below the minimum acceptable rate of 2 percent, the rate below which lending and investing allegedly simply do not pay. Whether full employment actually requires a rate of return of zero, 1 percent, 1½ percent, or a negative rate of return, the rate is allegedly just too low to make investment worthwhile. And thus, if somehow full employment were achieved, say the Keynesians, savings would be hoarded rather than invested. The effect would be a drop in spending for output and labor and a reduction in output and employment below the full-employment level. This would go on until sufficient movement had taken place up and to the left along the *IS* curve to raise the rate of return on capital back up to the 2 percent figure, the alleged minimum acceptable rate of return.

(In the preceding discussion, I have not dealt explicitly with the so-called *LM* curve. The relevant portion of it is present in the horizontal line representing the alleged minimum acceptable rate of return of 2 percent, and which is intersected by the *IS* curve in Figure 18–2. As wage rates and prices fall, according to the Keynesians, and less and less money is required in the form of

“transactions balances” to provide the spending necessary to buy the same physical product at lower prices, funds allegedly pile up in “speculative balances.” At a rate of return of 2 percent, the potential accumulation of speculative balances is allegedly infinite.²²)

Figure 18–3, which combines the *IS* curve of Figure 18–2 with the aggregate demand and supply curves of Figure 18–1, shows precisely how the *IS* curve is supposed to set the allegedly fixed limit of aggregate demand.²³ The horizontal axes of both diagrams are exactly the same. In the upper diagram, depicting the *IS* curve, output and employment are limited to the point marked $Y_{2\%}$. This is because that is the volume of output and employment at which the rate of return on capital is 2 percent. Any greater volume of output and employment would allegedly require a rate of return below 2 percent, which is unacceptably low and which would induce the hoarding of savings and drive the volume of output and employment back down (viz., to the left) and the rate of return back up. Equilibrium would allegedly be reached only at the respective values of $Y_{2\%}$ for output and 2% for the rate of return. This is the situation with respect to the *IS* curve, in the upper diagram of Figure 18–3.

The vertical aggregate demand curve *DD*, in the lower diagram of Figure 18–3, is drawn precisely at the point where the volume of output and employment allegedly bring the rate of return on capital on the *IS* curve down to 2 percent. *DD* cannot be one iota to the right of where it is, say the Keynesians, because if it were, the rate of return on capital invested would be below the minimum acceptable rate of 2 percent on the *IS* curve shown in the upper diagram. Thus, say the Keynesians, the aggregate demand curve of Figure 18–3 cannot possibly move to

the right to coincide with the aggregate supply curve that reflects output at the point of full employment. It cannot, it is argued, because, if it did, the rate of return on capital would be zero, as shown by the *IS* curve in the upper diagram, at the point of output corresponding to full employment. Indeed, the aggregate demand curve allegedly cannot move so much as a hair's breadth to the right without reducing the rate of return below the minimum acceptable level, as shown by the position of the rate of return on the *IS* curve.

Thus the Keynesian argument is that *full employment cannot exist, because if, somehow, it did, the rate of profit would be too low*. Businessmen would then start to hoard, and the hoarding would reduce output and employment until the rate of profit was raised back up to an acceptable

level. This is supposed to be the reason why a fall in wage rates and prices is unable to achieve full employment.

The underlying problem, allegedly, is that the *physical output* corresponding to full employment imposes an unacceptably low rate of return on capital. The level of wage rates and prices is thus held to be irrelevant. Employment and output cannot get beyond where they are, no matter what happens to wage rates and prices, according to the Keynesians, because if they did, the rate of return on capital would be lower than it is, which is already the minimum acceptable rate. Thus, say the Keynesians, the only effect of a fall in wage rates and prices would be a reduction in the volume of spending for the same amount of goods and labor, not any increase in employment and output.

Figure 18-3
The *IS* Curve Sets the Limit to Aggregate Demand

Figure 18-4
The Derivation of the IS Curve

Now some people may object to the Keynesian analysis that there is no good reason for picking 2 percent as the minimum acceptable rate of return—that employment and output should be able to expand so long as the rate of return on capital remains above zero, because earning any positive rate of return is better than earning none at all. This criticism, of course, could not meet the argument that the rate of return at full employment would have to be less than zero. Moreover, the Keynesians have various arguments in favor of taking 2 percent as the practical lower limit of acceptability for the rate of return. It would be possible to present and then refute these arguments. It would also be possible to show why full employment would be compatible even with a negative rate of return (because the prospect would still exist of any given individual employer earning a positive rate of return and thereby continuing to have a sufficiently strong motive for investing). Instead, however, I prefer to challenge the *IS* curve—the very notion that as employment and output expand, the rate of return on capital falls.

In order to accomplish this, it is necessary to explain the process by which the Keynesians derive the *IS* curve from various other real or imagined relationships. These relationships are: (1) the production function, (2) the saving function, (3) an equality of saving and investment, and (4) the marginal-efficiency-of-capital schedule. All of them, and the derivation of the *IS* curve from them, are shown in Figure 18–4 as a set of five interconnected diagrams. The production function appears in the diagram in the bottom-left portion of Figure 18–4; the saving function, in the diagram in the top-left portion; the equality of saving and investment, in the diagram in the top-right portion; the marginal efficiency of capital schedule, in the diagram in the center-right portion of the figure; and, finally, the *IS* curve, in the diagram in the center-left portion of the figure.

“Production function,” it should be recalled from Chapter 13, is simply the technical name given to the relationship between the volume of employment (labor performed) and the volume of output that results, given the state of technology and the supply of capital equipment. The labor performed is shown on the vertical axis, while the output produced is shown on the horizontal axis. This, of course, is a relationship that is in no way specific to Keynesian economics.²⁴ The use of the letter *N*, however, to measure the volume of employment is taken from the practice of the Keynesian textbooks.

The “saving function” is the Keynesian doctrine that a definite, determinate mathematical relationship exists between the level of income, on the one side, and the volume of saving out of income, on the other. In the diagram, saving is shown on the vertical axis and income on the horizontal axis. The saving function is the corol-

lary of the more widely known Keynesian doctrine of the “consumption function,” according to which consumption spending is mathematically determined by the level of income. It is derived by subtracting the consumption function from income. Typically, it is presented as the algebraic formula

$$S = -a + (1-c)Y,$$

where *a* is a given amount of consumption that occurs irrespective of the level of income, *c* is the “marginal propensity to consume,” viz., the extra consumption that take place out of additional income, and *Y* is national income/net national product. A minus sign appears before the constant *a* to indicate the amount of dissaving that would occur if income were zero. Since all income is either consumed or saved, and *c* is the marginal propensity of consume, *1-c* is the “marginal propensity to save.”

It should be noted that there is more than a little equivocation in the way the symbol *Y* is used. When it appears in connection with the production function, it refers to *physical output*—to “real income.” When it appears in connection with saving, however, it becomes *money income*, out of which cash hoarding occurs. Please note in this connection that the horizontal axis of the production function and the saving function are presented as identical, and so is the horizontal axis of the *IS* curve. *Y* is the measure of all three.

The third diagram—the equilibria of saving and investment—in the upper-right portion of Figure 18–4, shows investment equal to saving at every point. The vertical axis of this diagram is identical with the vertical axis of the saving-function diagram. Thus it too represents saving. The equality of investment, which is shown on the horizontal axis, with saving, is accomplished by the drawing of a 45-degree line through the origin. Every point on this line represents an equal distance on both axes of the diagram, and thus represents an equality of saving and investment. The purpose of this diagram is to set the stage for showing why investment cannot in fact be equal to saving when saving is substantial. Its purpose is to ask what would happen if all that were saved at every level of real income were actually invested.

The answer to this last, and very critical question is supposedly supplied in the fourth diagram, the marginal-efficiency-of-capital schedule—*mec* schedule for short—in the center-right portion of Figure 18–4. Here, the horizontal, investment axis of the diagram above is repeated, while the rate of return on capital is shown on the vertical axis. It is claimed that the greater is the volume of net investment, the lower is the rate of return on capital. This is shown by the *mec* schedule sloping downward to the right, with the greater being the size of *I*, the

smaller being the size of r . (The reasons advanced in support of the *mec* doctrine will be presented shortly. For the moment, it can be taken at face value, simply in order to understand the derivation of the *IS* curve. It is important to note in this connection, that the vertical axis of the *mec* schedule and the vertical axis of the *IS* curve are also identical.)

Given the production function, the saving function, the equilibria of saving and investment, and the *mec* schedule, the derivation of the *IS* curve is not difficult. We can begin by picking a low level of employment. Let us take point N_0 on the vertical axis in the bottom-left diagram. Reading over to the production function, along the dashed line, we see that this implies a definite level of output (real income). Call that level of output Y_0 . Now we read up a dashed line, all the way to the saving function. There, we find that Y_0 output (income) implies S_0 of saving. Reading across, along the dashed line, to the investment-equals-saving diagram, we find that S_0 of saving requires I_0 of net investment, if the saving is not to be hoarded. Reading down now, along the dashed line to the *mec* schedule, we find that I_0 of net investment implies an r_0 rate of return. If we now connect the Y_0 output produced by the N_0 volume of employment, with the r_0 rate of return that results from the investment of the savings generated by that level of output (income), we have a point on the *IS* curve.

Down in the bottom-left diagram, let us pick a second, higher level of employment on the vertical axis, namely, the amount denoted by N_1 . Reading over to the production function, we see that this implies another definite level of output—a higher one. Call it Y_1 . Again, we read up along the dashed line to the saving function. There we find a second, higher level of saving. Call it S_1 . Reading across to the saving-equals-investment diagram, we find that S_1 of saving requires equivalent I_1 of investment, if the saving is not to be hoarded. Reading down to the *mec* schedule, we find that I_1 of investment implies a lower, r_1 rate of return. If we now connect the r_1 rate of return with the Y_1 level of output, we obtain a second point on the *IS* curve. This is a point of greater output and a lower rate of return. What is present here is that more employment means more output (real income), more saving, the need for more investment to prevent the hoarding of that saving, and a lower rate of return on investment, if that investment actually takes place.

Finally, let us pick a third, still higher level of employment on the vertical axis in the production-function diagram. Let us call it “full employment, and denote it by the letters N_f . Once more reading over to the production function along a dashed line, we find that the higher level of employment goes with a higher level of output. Call this level of output Y_f , the full-employment level of

output. Reading up along the dashed line to the saving function, we see that there is a higher level of saving corresponding to the full-employment level of output. Call it S_f , the full-employment level of saving. Reading over to the saving-equals-investment diagram, we see that S_f of saving, if it is not to be hoarded, requires the correspondingly larger amount I_f of net investment. Reading down to the *mec* schedule, we see that I_f of net investment is accompanied by a further reduction in the rate of return to r_f , the full employment rate of return. The r_f rate of return and the Y_f level of output constitute a third point on the *IS* curve. Unfortunately, say the Keynesians, this rate of return is simply below the minimum acceptable rate of return of 2 percent, and so full employment cannot be achieved, or if somehow achieved, cannot be maintained.

A fall in wage rates and prices is held to be useless in achieving full employment because all of the above relationships are supposed to hold true *in physical terms*. N_f of employment means Y_f of output, means S_f of saving, requiring I_f of net investment, which causes too low a rate of return. These same physical relationships allegedly hold irrespective of the wage-and-price level. Specifically, at a lower wage-and-price level, it is held, no more physical investment is profitable (yields more than 2 percent) than before.

If, for example, initially there is 250 of investment at a 2 percent rate of return and, say, approximately 10 percent unemployment, a fall in wage rates and prices to $\frac{9}{10}$ their initial level will not achieve full employment—indeed, it will supposedly not achieve any increase in employment at all. This is because investment will allegedly have to fall 10 percent to 225—that is, in full proportion to the fall in wage rates and prices. It is claimed that investment must fall in this way because all the investment that there is room for at a 2-percent-or-greater rate of return is, allegedly, *that physical amount of investment*—for example, so many steel mills, cement factories, bicycle shops, and so forth—which at the initial price-and-wage level requires 250 to purchase. At a price-and-wage level $\frac{9}{10}$ as high, that physical amount of net investment requires only 225 to purchase. Net investment cannot remain at 250 in money, because then 250 of monetary net investment would be equivalent to approximately 278 of net investment at the initial price-and-wage level (viz., at $\frac{9}{10}$ times the initial price-and-wage level, 250 would be equivalent in buying power to $\frac{10}{9}$ times 250, which is 278). This greater physical amount of net investment would mean a rate of return below 2 percent. Thus, all that net investment can be at the $\frac{9}{10}$ price-and-wage level is 225, because now 225 represents the alleged maximum physical quantity of net investment that is profitable.

In exactly the same way, if the wage-and-price level were to fall all the way to half, the monetary amount of net investment would supposedly have to fall in half—to 125 from 250. It allegedly could not remain at 250 or even at 225, because monetary amounts of net investment at those levels would now represent real, physical net investment equivalent to what 500 purchased at the initial price-and-wage level, or what 450 would purchase at $\frac{9}{10}$ the initial price-and-wage level. Such volumes of net investment would allegedly thus result in a rate of return all the more below 2 percent. At a halved wage-and-price level, net investment cannot get beyond 125 in money, it is held, because that sum now represents the maximum physical amount of net investment that is profitable.²⁵

These results are shown in Figure 18–5. Below the horizontal axis in this figure are three different scales of measurement of net investment, each one corresponding to a different price-and-wage level, namely, the initial price-and-wage level, one that is $\frac{9}{10}$ as high, and one that is only half as high. Because the same maximum physical amount of net investment is allegedly all that is profitable—namely, the amount that is profitable down to a rate of return of 2 percent and no lower—the effect is that each successive scale of measurement at lower prices and wages moves correspondingly to the right. Thus, the net

investment that initially required 250 to purchase, successively requires only 225, and then only 125. Continued net investment in the amount of 250 at the $\frac{9}{10}$ price-and-wage level, and then at the halved price-and-wage level, would allegedly result in rates of return on capital respectively equivalent to those produced by 278 and 500 of net investment at the initial price-and-wage level

Thus, despite the fall in wage rates and prices, the problem that allegedly remains is that there cannot be an outlet for saving in excess of the given physical amount of net investment that is profitable (i.e., that yields 2 percent or more). And thus there cannot be a real income (output) that results in any such greater level of saving, nor, finally, a volume of employment that would result in any such level of output. The volume of employment is thus allegedly limited to that amount that results in a level of output (real income) out of which saving is no greater than is consistent with the allegedly limited physical volume of profitable investment opportunities.

In other words, according to the Keynesians, there cannot lastingly be a level of employment, output, and real income greater than what produces the limited volume of saving that can be accommodated by the limited volume of profitable investment opportunities. If the volume of employment is greater than the one that pro-

Figure 18–5
The MEC Schedule

At initial p and w level:	50	100	150	200	250	300	350	400	450	500
At $\frac{9}{10} p$ and w level:	45	90	135	180	225	270	315	360	405	450
At $\frac{1}{2} p$ and w level:	25	50	75	100	125	150	175	200	225	250

duces such a limited level of saving, then saving supposedly exceeds the limited profitable investment opportunities that exist, thereby driving the rate of return on capital below the minimum acceptable level. The alleged consequences are that hoarding results, spending drops, and sales revenues, employment, and output all decline. Their decline then represents a drop in real income. Out of the smaller real income, less saving occurs. The drop in employment, output, and real income must allegedly be great enough to reduce the volume of saving to the point where it no longer exceeds the allegedly limited profitable investment opportunities available.

In sum, full employment, or any employment beyond a fixed, given amount, cannot exist, or at least cannot be maintained, according to the Keynesians, because it would produce a physical volume of output out of which there would be a physical volume of saving requiring a physical volume of net investment that would put the rate of return below the minimum acceptable rate. In essence, the Keynesian argument is that full employment cannot exist in a free economy because if it did, the economic system would, in effect, choke on the allegedly excessive saving that would accompany full employment. Keynes himself states the essence of his position in the following words (where helpful, I insert my own clarifications in brackets):

Perhaps it will help to rebut the crude conclusion that a reduction in money-wages will increase employment “because it reduces the cost of production”, if we follow up the course of events on the hypothesis most favourable to this view, namely that at the outset entrepreneurs *expect* the reduction in money-wages to have this effect. It is indeed not unlikely that the individual entrepreneur, seeing his own costs reduced, will overlook at the outset the repercussions on the demand for his product and will act on the assumption that he will be able to sell at a profit a larger output than before. If, then, entrepreneurs generally act on this expectation, will they in fact succeed in increasing their profits? Only if the community’s marginal propensity to consume is equal to unity, so that there is no gap between the increment of income and the increment of consumption [i.e., there is no additional saving]; or if there is an increase in investment, corresponding to the gap between the increment of income and the increment of consumption, which will only occur if the schedule of marginal efficiencies of capital has increased relatively to the rate of interest [i.e., either the *mec* schedule must somehow move to the right, which there is allegedly no reason for its doing, or the rate of interest must fall, which it can’t do, if it is already at 2 percent]. Thus the proceeds realised from the increased output will disappoint the entrepreneurs and employment will fall back again to its previous figure, unless the marginal propensity to consume is equal to unity [i.e., there is no additional saving] or the reduction in money-wages has had the effect of increasing the schedule of marginal efficiencies of capital relatively to the rate of interest and hence

the amount of investment [Keynes means, of course, increase the amount of investment that is profitable—i.e., yields 2 percent or more]. *For if entrepreneurs offer employment on a scale which, if they could sell their output at the expected price, would provide the public with incomes out of which they would save more than the amount of current investment, entrepreneurs are bound to make a loss equal to the difference; and this will be the case absolutely irrespective of the level of money wages.*²⁶

I have italicized the last sentence because if any single sentence of Keynes can express the theoretical substance of his doctrine, that is the one.²⁷

The Grounds for the *MEC* Doctrine

It should be obvious that the two critical doctrines underlying the *IS* curve are the doctrines of the saving function and, above all, the declining *mec* schedule. According to the saving function, people insist on saving a significant portion of the additional real income corresponding to the additional output that results from additional employment. If they did not do so—if there were no additional savings requiring investment as employment increased, full employment might actually be achieved according to Keynes, as the passage quoted above makes clear. For the rate of return on capital would then not have to fall as employment increased. Thus, if only people were sufficiently profligate, they could be prosperous, says Keynes.

Fortunately, of course, people do wish to save. From the perspective of Keynesian economics, however, this creates the problem of having to prevent the resulting savings from being hoarded, because of the alleged decline in the rate of return on capital that results from their being invested.

It is now necessary to present the reasons Keynes and his followers advance in support of the declining *mec* doctrine—of the claim that as net investment increases, the rate of return on capital must fall. Keynes himself writes:

If there is an increased investment in any given type of capital during any period of time, the marginal efficiency of that type of capital will diminish as the investment in it is increased, partly because the prospective yield will fall as the supply of that type of capital is increased, and partly because, as a rule, pressure on the facilities for producing that type of capital will cause its supply price to increase . . . Thus for each type of capital we can build up a schedule, showing by how much investment in it will have to increase within the period, in order that its marginal efficiency should fall to any given figure. We can then aggregate these schedules for all the different types of capital, so as to provide a schedule relating the rate of aggregate investment to the corresponding marginal efficiency of capital in general which that rate of investment will establish. We shall call this the investment demand-schedule; or, alternatively,

the schedule of the marginal efficiency of capital.²⁸

When Keynes speaks of rising “supply prices” of capital assets as investment demand increases and causes pressure on the facilities for producing capital goods, what he has in mind is the notion that more net investment constitutes additional demand for capital assets and thus raises their prices. His further belief that increasing net investment results in declining yields to capital assets is based in part on the conviction that as more productive capacity is brought into existence, as the result of the net investment, the selling prices of products will fall because of their larger supply. In addition, the yields to capital assets will allegedly fall because of the operation of the law of diminishing returns: successive equal increments of net investment, even at constant purchase prices of capital assets, supposedly result in diminishing physical returns to the successive doses of capital assets purchased.²⁹

To express these ideas in terms of a simple example, we might imagine that initially the price of a machine that turns out widgets is \$1,000 and that its use enables the same quantity of labor to produce 10 additional widgets every year, which have a selling price of \$10 each. On the simplifying assumptions that this machine will last forever and that the cost of materials and fuel can be ignored, the implied rate of return is 10 percent per year: 10 additional widgets times \$10, divided by \$1,000. Now, however, there is a demand for two such machines. As a result, the purchase price rises above \$1,000—say, to \$1,050. In addition, the selling price of widgets will fall somewhat, because of their larger supply—say, to \$9.50. Finally, because of diminishing returns, it may be possible to obtain only 9 additional widgets instead of 10 by virtue of the employment of the second machine. The operation of any one of these factors, it is held, reduces the rate of return. Their combined operation in this example must reduce the rate of return to not much more than 8 percent: \$9.50 times 9 widgets, divided by \$1,050. In these ways, more net investment is held to reduce the rate of return on capital.³⁰

The Keynesian Solution: “Fiscal Policy”

The Keynesian solution to the alleged unemployment equilibrium of capitalism is government budget deficits (euphemistically called “fiscal policy”). The purpose of the budget deficits is to absorb the excess saving that allegedly would otherwise take place at full employment. Figure 18–6 shows the nature of the gains the Keynesians believe government budget deficits achieve.

The diagram in Figure 18–6 is the same as that in the upper-right portion of Figure 18–4—that is, the saving-equals-investment diagram. But it shows investment as

equal to saving minus the deficit, instead of saving in full. The deficit, according to the Keynesians, serves as an additional outlet for saving and thus reduces the amount flowing through to net investment. This is shown in the diagram by the drawing of a second 45-degree line, above the first one by a vertical distance equal to the amount of the deficit, which is represented by d on the vertical axis. This new 45-degree line is labeled $S - d = I$ —saving minus the deficit equals net investment—in contrast to $S = I$, which is the label describing the first 45-degree line. Note that when saving equals the deficit, investment equals zero, as shown by the intersection of the new 45-degree line with the vertical axis at point d . Because both are 45-degree lines, the new line is not only above the original one by the amount of the deficit but also to the left of it by the amount of the deficit. This depicts the idea that every given amount of saving now requires an amount of investment that is less than itself by the amount of the deficit.

The crucial result is supposed to be that for any given level of employment, output, and saving, the amount of investment required to prevent hoarding is less than it otherwise would be by the amount of the deficit. Since there is less investment, the further crucial result is supposed to be that the rate of return on capital is now higher for any given level of employment, output, and saving. By the same token, it takes more employment, output and saving to achieve the same rate of return as previously. *In other words, the effect of the deficit is supposedly to shift the IS curve up and to the right.*

This result is confirmed by drawing the new saving-

Figure 18-7
How Budget Deficits Are Supposed to Promote Full Employment

minus-the-deficit-equals-investment line in the upper-right diagram of Figure 18-4 and then examining the effect on the *IS* curve. Each *N*, *Y*, and *S* point will be found to go with a lower *I* and thus a higher *r* point. This is shown in Figure 18-7, which, in essence, substitutes Figure 18-6 for the upper-right diagram of Figure 18-4.

What the set of diagrams in Figure 18-7 purports to show is that, thanks to the government's budget deficit, for any given volume of employment, output, real income, and saving, there is less investment and thus a higher rate of return on capital than before. Thus, there can be more employment, output, real income, and saving before the volume of investment becomes so large as to push the rate of return on capital to the minimum acceptable level of 2 percent. With a large enough deficit, argue the Keynesians, there can be full employment.

The whole process is described by the upward and rightward movement of the *IS* curve. Following along the dashed lines, notice how the same magnitudes of employment, N_0 , N_1 , and N_f , continue to result in the same magnitudes of output (real income) and saving—namely, Y_0 , Y_1 , and Y_f and S_0 , S_1 , and S_f respectively. But now S_0 of saving requires less than I_0 of net investment; S_1 of saving now requires less than I_1 of net investment; and, what is supposedly critical, S_f of saving now requires sufficiently less than the old I_f volume of net investment that full employment can now take place at a rate of return above 2 percent. The new relationships to investment and the rate of return are indicated by lines composed of plus signs, which run downward from the saving-minus-the-deficit-equals-investment line to the *mec* schedule and then across, to the left, to the various values of *Y* resulting from the various values of *N*.

To describe matters verbally, one could say this: The alleged problem of capitalism, according to the Keynesians, is that full employment results in a volume of saving that the economic system cannot profitably invest. In effect, such saving is a destructive by-product of full employment under capitalism, and thus prevents the existence of full employment. It is a kind of toxic excrescence—a veritable boil on the economic body that interferes with its vital functioning. Fortunately, however, there is a doctor, and he has a cure for the problem. The doctor is the government, and the cure is a deficit in its budget. As Keynes has explained matters, the government doctor will lance the savings boil and allow its destructive juices to flow into the waiting pan of the government's deficit rather than into private investment, where it would reduce the rate of return on capital to an

intolerably low level.

A different, perhaps less distasteful analogy can be used. Capitalism, we might imagine, cannot have full employment because of the existence of a hard-drink function, rather than a saving function. As employment and real income rise, people feel themselves able to afford to drink more. At the point of full employment, they drink so much that they are physically hung over on the week ends to such an extent that they are incapable of work on Mondays. This too would represent a kind of "unemployment equilibrium." Once again, a case might be made for the intervention of the good government doctor: it might siphon off people's liquor money with the sale of soft drinks, 2 percent beer, or perhaps even methadone. Or, perhaps, it might work to divert their liquor money onto ecclesiastical collection plates, in effect, buying bonds issued in the name of heaven rather than in its name.

Innumerable analogies to the unemployment-equilibrium doctrine can be created on the basis of environmentalism. That doctrine, of course, holds that economic activity is replete with self-destructive by-products.³¹ On the basis of it, one could easily invent all kinds of mathematical functions analogous to the "saving function." Then all one would need to do is arbitrarily assert some fixed limit to the capacity of the world to cope with the particular by-product. On that basis, one could proceed to argue that employment and production must be limited to the point of not generating an amount of such by-product in excess of the alleged fixed limit. Indeed, this is precisely what the environmentalists are doing in the cases of carbon dioxide emissions and garbage disposal. Only instead of seeking to impose an unemployment equilibrium by forcibly holding down the volume of employment, they seek to impose limits on the productivity of labor and the volume of consumption. But just as with Keynesianism and its budget deficits, there is still an alleged need for the good government doctor (though not as often, because the environmentalists believe that human suffering is fundamentally inescapable and, indeed, desirable). In the case of the carbon dioxide emissions, it is sometimes argued that the alleged low-productivity-of-labor equilibrium might be overcome to some extent by virtue of government imposed tree-planting programs. These would play the same kind of role in the absorption of allegedly harmful carbon dioxide as government budget deficits are supposed to play in the absorption of allegedly harmful saving. The essential common element in Keynesianism and environmentalism is the belief that free individuals are engaged in essentially self-destructive activity that, if it can be remedied at all, can only be remedied by the coercive power of the state.

3. Critique of the *IS-LM* Analysis

The Declining-Marginal-Efficiency-of-Capital Doctrine and the Fallacy of Context Dropping

The critique of the Keynesian *IS-LM* analysis can be concentrated on the declining-marginal-efficiency-of-capital doctrine. The Keynesians' use of this doctrine is a prime example of a major logical fallacy identified by Ayn Rand, which she calls "context dropping."³² Context dropping is the fallacy of denying, forgetting, or otherwise contradicting the context that is explicitly or implicitly under discussion. An example of context dropping from outside the field of economics is the following. Imagine a group of aeronautical engineers who are working on the problem of how to increase the speed of an airplane. They know that other things being equal, the lighter the weight of the plane, the faster it will fly. If, to make the plane lighter, they concluded that its engines should be eliminated, they would be committing the fallacy of context dropping. For the context under discussion is the flight of a heavier-than-air machine, which is possible only by virtue of its possession of engines. Another example of context dropping would be an esoteric discussion of the effects of living or working on the tenth floor of a building, which discussion somehow managed to deny or otherwise contradict the existence of any one or more of the lower nine floors of the building or of its foundation.

The use of the declining-marginal-efficiency-of-capital doctrine is an example of context dropping, for the following reasons. The context under discussion is the question *can a fall in wage rates and prices achieve full employment or can it not?* This question is the context which must always be kept in mind. It is the context within which the declining-marginal-efficiency-of-capital doctrine is advanced, in order to show why a fall in wage rates and prices cannot achieve full employment. Yet, as will quickly be made apparent, every one of the three grounds advanced in support of the declining-marginal-efficiency-of-capital doctrine, and which were described in the previous section, flatly *contradicts* the context under discussion.

Once again, the context under discussion is the ability of *lower* wage rates and prices to achieve full employment. This context, of course, implies lower unit costs of production, for that is what lower wage rates achieve both directly and through bringing about lower prices of materials and machinery and capital goods in general. The achievement of full employment also implies the availability of more labor in production relative to the existing supply of capital goods. In a state of mass unemployment, the factories and machinery exist in vir-

tually the same quantity as before the onset of the depression and the unemployment. But they are largely idle. The ratio of capital to labor employed is correspondingly high. As full employment is approached, and more and more workers return to the factories, the ratio of capital to labor correspondingly falls.

Now this whole context is contradicted by the use of the declining-marginal-efficiency-of-capital doctrine to show why a fall in wage rates and prices cannot achieve full employment.

The use of the declining-marginal-efficiency-of-capital doctrine enables the Keynesians to end up claiming that a *fall* in wage rates and prices cannot achieve full employment, precisely by dropping the context of a fall in wage rates and prices and rise in employment, and switching to an altogether different, indeed, *opposite* context, which could exist only if wages rates, production costs, and prices rose instead of fell. For the context to which the Keynesians deftly switch is one of a *rise* in the prices of capital assets, *no* fall in the costs of production but constant or, indeed, *rising* costs of production, and no increase in the quantity of labor employed relative to the supply of capital goods in existence, but, on the contrary, a further increase in the supply of capital goods relative to the supply of labor that is employed.

Recall that the first reason advanced in support of the falling marginal efficiency of capital was the claim that as more net investment took place to offset the additional saving accompanying the additional employment, the prices of capital assets would *rise*, in response to the increase in demand for capital assets allegedly constituted by the additional net investment. The actual fact is, of course, that in the context of the elimination of unemployment by means of a fall in wage rates and prices, the prices of capital assets would *fall*, not rise. Keynes and his followers thus totally contradict the context under discussion. They claim that a fall in wage rates and prices cannot achieve full employment, because if, *instead of falling*, as they necessarily would in these circumstances, the prices of capital assets *rose*, the rate of return on capital would be reduced.

Furthermore, it is curiously ironic that in arriving at their bizarre conclusion that the prices of capital assets would rise in the midst of a fall in wage rates and prices, the Keynesians commit precisely the fallacy that the arch-Keynesian Professor Samuelson is at such pains to warn new students of economics against. Namely, the fallacy of confusing the increase in the quantity of a good demanded that takes place in response to a lower price of the good, with an increase in the demand for the good.³³ Precisely this fallacy is what is present in the Keynesians' belief that the rise in net investment that accompanies the fall in wage rates and prices and the

restoration of full employment, constitutes a rise in the demand for capital assets and thus acts to raise their prices. The fact is that the additional net investment presupposes and is in response to *lower* prices of capital assets, and can endure only so long as the prices of the capital assets are lower. It does not operate to raise those prices. And this is true even if one were to grant the legitimacy of conceiving of the additional net investment as representing an additional total expenditure of money for the capital assets. It would still be necessary to keep in mind that the larger expenditure of money was in response to lower prices and could endure only so long as the prices of capital assets remained lower.³⁴

Recall that the second reason advanced for the declining marginal efficiency of capital was the claim that more net investment means more capacity in place, which means lower selling prices of products, which, other things being equal, means a fall in profitability. Here the context dropping consists of forgetting that other things—namely, the costs of production—are *not* equal. Precisely a *fall* in wages and costs is what brings about the additional production and the decline in prices. Lower prices founded on lower costs of production do *not* reduce profitability or the so-called marginal efficiency of capital.

Again, the Keynesians contradict the context. They argue that a fall in wages, costs, and prices cannot achieve full employment because if all that occurred were the fall in selling prices and *no fall in costs*—indeed, a rise in costs because of the alleged rise in the prices of capital assets—the rate of return on capital would fall. This, of course, is totally absurd. It is absurd to argue against the ability of a fall in wage rates and costs of production to achieve full employment on the grounds that if there were *no* fall in costs of production but, somehow, only a fall in the prices of the products, full employment could not be achieved. This dropping and switching of context enables the Keynesians to fail to see that the lower selling prices of products are offset and in fact more than offset by a fall in costs of production, and thus that there is not only no fall in the rate of profit (the “marginal efficiency of capital”), but an actual *rise* in the rate of profit in consequence of the fall in wages and costs of production.

Finally, it should be recalled that the third reason advanced in support of the declining marginal efficiency of capital was the claim that diminishing returns would accompany the additional net investment that was required to offset the additional saving taking place as employment, output, and real income expanded. Now putting aside the actual irrelevance of the law of diminishing returns to the rate of profit, and assuming for the sake of argument that it did have a determining effect, the truth is that in the context of a fall in wage rates and

prices and increase in the volume of employment and output, the physical returns to capital goods would *increase* rather than decrease. This is because as the economic system moves from mass unemployment to full employment, *the supply of labor employed in production increases at a more rapid rate than the supply of capital goods*. This is so because in the conditions of mass unemployment a substantial supply of capital goods previously used in production continues to exist in the form of idle machines and factories. Its existence relative to the diminished number of workers employed constitutes an unusually high ratio of capital to labor. As the workers come back into the factories and once again take up the use of these capital goods, the ratio of capital to labor sharply declines.

Such increase in the supply of capital goods as occurs as the result of additional employment, output, real income, and saving is a purely derivative phenomenon. The fundamental, primary phenomenon is the increase in the ratio of labor employed to capital goods, which implies increasing returns to capital goods, not decreasing returns. If ever there were a problem of too-low physical returns to capital goods, nothing could be a surer cure than the employment of more labor. Whatever problem might be imagined to exist, it would necessarily be less at the point of full employment than at the point of mass unemployment, or any unemployment.

As an illustration of this fact, imagine that in conditions of unemployment there are 12 units of capital goods and 3 workers employed, who produce a net output of 3 units of goods. The achievement of full employment means, let us assume, the employment of 4 workers who produce a net output of 4 units of goods. If fully one-half of the additional net output of 1 unit is saved, the ratio of capital goods to labor still falls dramatically—from 12 to 3 (i.e., 4:1), to 12.5 to 4 (i.e., to 3.125:1). And this principle continues to hold, even if it were the case that the long-term continuation of full employment and steady saving and net investment of a half a unit of net output per year ultimately resulted in a ratio of capital to labor of, say, 24 to 4 (i.e., 6 to 1) at the point of full employment. This is because in that case, with the same unemployment as before, the ratio of capital to labor would be 24 to 3 (i.e., 8 to 1). Thus, the movement from unemployment to full employment would still reduce the ratio of capital to labor and increase the physical returns to capital goods, not decrease them.

The procedure of the Keynesians, of course, is to forget the existence of the fundamental phenomenon, the increase in the supply of labor employed as the economic system goes from unemployment to full employment, and to focus on the secondary, derivative phenomenon, the increase in the supply of capital goods that results

from the saving out of the net output of the additional workers employed. In this way, the Keynesians proceed to assume that the ratio of capital goods to labor rises and the physical returns to capital goods fall, at the very time that exactly the opposite is true. Thus, the Keynesians end up claiming that full employment cannot take place on the grounds that if extra employment did *not* mean an increase in the ratio of labor to capital, but somehow the opposite, namely, an increase in the ratio of capital to labor, full employment could not exist—by virtue of the too-low rate of profit allegedly resulting from the relative overabundance of capital goods. In a word, the Keynesians end up denying that full employment can exist by confusing the effects of its existence with the effects of its nonexistence.

Indeed, the whole process by which the Keynesians reach the conclusion that a fall in wage rates and prices cannot achieve full employment is nothing more than a *refusal to consider its actual existence*. Instead of considering the existence of a fall in wage rates, costs, and prices and the employment of a larger number of workers, they choose to consider the totally different and opposite case of a rise in the prices of capital assets, of no fall in the costs of production but only in the selling prices of products, and of no increase in the supply of labor employed but only of an increase in the supply of capital goods that derives from that employment. Then, on the basis of their consideration of this totally opposite and thoroughly illegitimate case, in which down has literally become up—namely, a fall in the prices of capital assets has become a rise in the prices of capital assets—and in which effects have been divorced from their causes—that is, the fall in selling prices has been divorced from its cause, the fall in wage rates and costs, and the additional net investment and capital accumulation has been divorced from its cause, which is the employment of additional workers with the capital goods already in existence—they conclude that they have proven something about the case at hand. All they have actually proven is their own capacity for confusion, if not intellectual dishonesty.³⁵

The Marginal-Efficiency-of-Capital Doctrine and the Claim That the Rate of Profit Is Lower in the Recovery from a Depression Than in the Depression

There are further major criticisms which must be made of the Keynesian analysis in connection with the marginal-efficiency-of-capital doctrine. The Keynesian claim that a fall in wage rates and prices cannot achieve full employment, because at full employment the rate of return on capital would be too low, is a claim that *the rate of return in the recovery from a depression is lower than it is in the depression*.

What the Keynesians claim is that the economic system cannot recover from mass unemployment and depression because if somehow it did, the rate of return on capital would fall—which means that it would be lower in the recovery from the depression than it was in the depression. In effect, the Keynesians tell us that if we think the rate of profit is low now, in the conditions of mass unemployment and depression, we should wait and see what it will look like in the recovery. In the state of mass unemployment and depression, it is already at the minimum acceptable level (in the neighborhood of 2 percent) and at full employment it would have to be lower still, they say. Indeed, according to the Keynesians, if somehow the economic system did temporarily manage to recover and achieve full employment, it would immediately have to return to the conditions of mass unemployment and depression as the means of *elevating* the rate of profit—above the still lower level that is supposed to exist in the recovery. This is the actual meaning of the whole Keynesian argument for the unemployment equilibrium. If there is any doubt about this fact, the reader should look once again at the standard Keynesian diagrammatic relationships presented above in Figure 18–4 of this chapter and reread the extensive passage quoted from Keynes himself some paragraphs later, in which he claims to “rebut the crude conclusion that a reduction in money wages rates will increase employment.”

The Unemployment-Equilibrium Doctrine and the Claim That Saving and Net Investment Are at Their Maximum Possible Limits at the Very Time They Are Actually Negative

An equally profound and closely related reversal of economic reality on the part of the Keynesian analysis is its belief that in a depression saving and net investment are at their maximum possible limits, and the problem is that full employment requires that they be carried still further.³⁶ This, of course, is the alleged proximate cause of the marginal efficiency of capital having to be pushed below its minimum acceptable level. The actual fact is, however, that far from being at their maximum limits, saving and net investment are extremely low or even *negative* in a depression. For example, in the Great Depression following 1929, corporate saving (undistributed corporate profits) was negative in every year from 1930 to 1936 and again in 1938; personal saving was negative in 1932 and 1933 and barely more than zero in 1934; net investment was negative in the years 1931 to 1935 and again in 1938.³⁷

There should be nothing surprising in these facts. They are logically implied in the very nature of a depression and mass unemployment. When people are out of

work, they must live off their savings. In a state of mass unemployment, the consumption of savings in this way is necessarily very considerable. At the same time, corporations are under pressure to continue to pay dividends to their stockholders, even though they are currently earning little or no profits. To pay dividends under such conditions, they must dip into their accumulated savings—their earned surplus accounts. Unincorporated businesses, of course, are under the same kind of pressure; they too must frequently continue to support their owners even though their current profits are insufficient to do so. In these ways, the current saving of those individuals and business firms who are still in a position to save out of income is more than offset, and saving in the economy as a whole becomes nonexistent or, indeed, becomes negative.

The fact that net investment becomes negative can be understood by direct inference, either from the fact that saving out of income becomes negative or from the fact that in a depression productive expenditure sharply declines, in particular productive expenditure for fixed assets, such as plant and equipment. A plunge in productive expenditure for fixed assets implies a fall in net investment, because at the same time depreciation charges hardly change at all, since they are based on a percentage of the productive expenditure for fixed assets made over a long period of prior years. Net investment in fixed assets actually becomes negative to the extent that current productive expenditure for fixed assets drops below depreciation charges. To that extent, the sum of the subtractions from the fixed asset accounts in the economic system exceeds the sum of the additions currently being made to those accounts, and thus the net change—the net investment—is negative.³⁸ Similarly, in a depression productive expenditure on account of inventory and work in progress plunges, while cost of goods sold, which reflects such productive expenditure made in prior periods, continues to hold up. To the extent that productive expenditure on account of inventory and work in progress drops below cost of goods sold in the economic system, the result is negative net investment in inventory and work in progress, because what is now signified is that the sum of the additions being made to these accounts correspondingly falls short of the sum of the subtractions. The reduction in the value of the inventory and work-in-progress accounts in the economic system is the extent of the negative net investment of this type.³⁹

The Marginal-Efficiency-of-Capital Doctrine's Reversal of the Actual Relationship Between Net Investment and the Rate of Profit

We are now in a position to make what is perhaps the most decisive objection of all to the declining-marginal-

efficiency-of-capital doctrine and the Keynesian analysis. And that is that our discussion of the determinants of the rate of profit has shown that the rate of profit and net investment are *positively related*. We have seen that net investment and profits move together virtually dollar for dollar, because while profits are the difference between sales revenue and costs, net investment is the difference between productive expenditure (which is almost equivalent to sales revenue) and those same costs.⁴⁰

Thus, the actual reason the rate of profit is so low or negative in a depression is the same as the reason net investment is so low or negative—namely, that productive expenditure has fallen, taking sales revenue with it, while costs, especially depreciation costs, fall only with a lag. By the same token, in the recovery from a depression *net investment and the rate of profit both improve together*. For every dollar by which productive expenditure rises relative to costs, creating net investment, sales revenues rise relative to those same costs, creating profits. Likewise, for every dollar by which costs fall relative to productive expenditure, also creating net investment, those same costs fall relative to sales revenues, creating profits. The mathematical implication of this virtual dollar-for-dollar equivalence between additional net investment and additional profits is that the rate of profit—the so-called marginal efficiency of capital—must actually *rise* with the rise in net investment, and not fall as the Keynesians maintain.

For example, if in the depths of a depression, aggregate profit in the economic system is 10, while total accumulated capital is 1,000, then the average rate of profit is a mere 1 percent. But if now net investment increases by, say, 50, then aggregate profit increases from 10 to 60. At the same time, of course, the total accumulated capital of the economic system rises to 1,050. The average capital outstanding over the period becomes 1,025—viz., the average of 1,000 and 1,050. However much it may come as a shock to the Keynesians, the unavoidable implication of these facts is that the average rate of profit rises from 1 percent to almost 6 percent! What happens mathematically is exactly the same sort of thing as happens to the season average of a baseball team that goes on a winning streak. In the case of the baseball team, its season average rises in the direction of 1,000. A thousand is its average over the course of its winning streak—its marginal average so to speak—and thus its season average rises accordingly. In the case of more net investment and equivalently more profit, the average rate of profit rises in the direction of a mathematical limit of 200 percent, for the additional net investment is accompanied by an equivalent addition to the amount of profit and by an addition only half as great to the average capital outstanding in the economic system.

As indicated, the rise in the rate of profit that must accompany more net investment in the recovery from a depression, has its counterpart in the fall in the rate of profit that accompanies the wiping out of net investment in the descent into a depression. In the latter case, the plunge in productive expenditure not only drives productive expenditure below costs, making net investment negative, but equivalently reduces sales revenues relative to the same costs. This drives profit in the economic system below net consumption. Profit comes to equal net consumption plus a negative net investment component.

In the light of the foregoing analysis, it is difficult to imagine a more erroneous conception of things than the Keynesian notion that the rate of profit is at a depression level because of too much net investment and that the further net investment that must accompany recovery from the depression will drive it still lower. The facts are that the rate of profit is low in a depression for the same reasons that net investment is low—to the point of being negative—and will rise with the rise in net investment. In other words, among the changes that would need to be made in the Keynesian analysis, if for some reason one had any wish to retain it, is a reversal of the slope of the so-called *mec* and *IS* curves in the context of recovery from a depression and the reestablishment of full employment. But since the Keynesian system is so thoroughly riddled with errors and contradictions, there is no point in attempting to modify it or retain it in any way. The Keynesian analysis is so wrong that it is beyond redemption. The one, fundamental change that is needed is its total abandonment.

The Contradiction Between the Marginal-Efficiency-of-Capital Doctrine and the Multiplier Doctrine

It is worth pointing out the existence of a major contradiction between the marginal-efficiency-of-capital doctrine and the multiplier doctrine. When they propound the marginal-efficiency-of-capital doctrine, the Keynesians claim that the effect of more net investment is a reduction in the rate of profit. Yet when they propound the multiplier doctrine, they claim that the effect of more net investment is a multiplied increase in aggregate demand. (In their absurdly narrow view of aggregate demand, of course, this means an increase in net national product, NNP, which is equal to the sum of net investment plus consumption, which in turn allegedly pay the national income.) The additional net investment, they tell us, brings about a diminishing series of additional consumption expenditures, which increases aggregate demand by a multiple of the initial increase in net investment.⁴¹

Now surely, if there is an increase in aggregate demand, aggregate profit must rise. Even on the highly conservative assumption that aggregate profit maintain-

ed merely a fixed percentage relationship to “aggregate demand,” instead of bearing a higher percentage relationship, as a rising demand actually implies, the greater the increase in net investment, the greater would be the increase in the rate of profit.

If, for example, profits were assumed to constitute a steady 20 percent of the national income, which, historically, is not an unreasonable figure, a multiplier of two would mean an increment of profits 40 percent as large as the increment of net investment. A multiplier of three would mean an increment of profits 60 percent as large as the increment of net investment, and so on. Even with a multiplier of only two, the rate of profit on accumulated capital would certainly have to rise as net investment increased, for it is certainly below 40 percent to begin with and would move in the direction of 40 percent on the basis of additional net investment. (Indeed, allowing for the fact that the average capital outstanding grows by only half of the additional net investment, the rate of profit would rise toward 80 percent rather than 40 percent.)

The contradiction between the multiplier doctrine and the declining-marginal-efficiency-of-capital doctrine is actually much more acute than this example indicates. For I have shown that virtually *all* of the increase in national income that would accompany the rise in consumption spending that the multiplier is supposed to bring about, would be profit income.⁴² Of course, I have also shown that the multiplier doctrine itself is totally fallacious. The fact that it totally contradicts the marginal-efficiency-of-capital doctrine, which, as shown, is also entirely fallacious, further adds to the indictment of the Keynesian analysis.

A Fall in Wage Rates as the Requirement for the Restoration of Net Investment and Profitability Along With Full Employment

Not only do net investment and the rate of profit improve together in the recovery from a depression, but precisely what is required for their improvement is *a fall in wage rates*. In the context of recovering from a depression, a fall in wage rates is necessary both for the restoration of productive expenditure and thus sales revenues, and for the write-down of the value of existing fixed assets and inventories, which operation reduces the costs deducted from productive expenditure and sales revenues. In both of these ways, a fall in wage rates increases net investment and profits. Thus, it not only brings about full employment, but restores net investment and profitability as well.

To elaborate, when wage rates fall to their new equilibrium level—a level corresponding to the reduced velocity of circulation of money and the reduced quantity

of money that follows the removal of the artificial monetary stimulus of the preceding boom—the costs of new investments are correspondingly reduced. In response, as I have repeatedly pointed out, investment expenditures which had been postponed, awaiting the necessary fall in wage rates and costs to the lower level, now take place, with the result that productive expenditure and thus sales revenues in the economic system are increased. At the same time, assets acquired in the previous boom at an artificially high level of costs, are written down to be competitive with the lower-cost investments that can now be made, as the result of the fall in wage rates. And this, of course, reduces the costs deducted from productive expenditure and sales revenues. In these ways, the fall in wage rates restores both net investment and profitability.

By the same token, as I have also pointed out before, the failure of wage rates to fall operates not only to prolong, but also to deepen the depression. To the extent that it causes the postponement of investment expenditures and the consequent wiping out of profitability, it adds to the inability of business firms to repay their debts. This, in turn, causes more bank failures, a further reduction in the quantity of money and velocity of circulation, and thus necessitates greater wage cuts to achieve full employment and recovery than would have been the case if the wage cuts had come quickly.⁴³

Wage Rates, Total Wage Payments, and the Rate of Profit

The preceding discussion has shown that when unemployment exists a fall in wage rates operates to increase total productive expenditure. As part of this process, it is virtually certain that total wage payments increase, with the result that the fall in wage rates is actually accompanied by a more than proportionate increase in the quantity of labor demanded, and thus by a more than proportionate increase in the volume of employment. However, it should be realized that the improvement in business profitability will tend to be the greater the *smaller* is the portion of the additional productive expenditure that takes the form of wage payments. Indeed, business profitability would increase the most if the fall in wage rates were accompanied by an actual fall in total wage payments and a correspondingly greater increase in the demand for capital goods.

The reason for these conclusions is that wage payments tend to show up relatively quickly as costs deducted from sales revenues. In contrast, outlays for machinery and plant show up much more slowly as costs deducted from sales revenues. Thus, if a billion dollars, say, of wage payments were replaced with a billion dollars of spending for plant and equipment, total busi-

ness profits might very well increase by almost the full billion dollars. This is because total business sales revenues would be unchanged: the demand for capital goods would rise by a billion dollars, while the wage earners' demand for consumers' goods would fall by a billion dollars. At the same time, depreciation cost, equal to a relatively small percentage of the billion dollars spent for the plant and equipment, would take the place of the much larger cost figure reflecting the payment of a billion dollars in wages. Thus, total profits in the economic system would rise—by virtue of aggregate sales revenues remaining whatever they were while aggregate costs deducted from sales revenues fell. Obviously the increase in net investment would also be correspondingly greater under these conditions.⁴⁴

This discussion should serve further to refute the popular Keynesian and labor-union doctrine that a fall in wage rates operates to intensify a depression by virtue of reducing total wage payments and thus consumer spending. The truth is that even if the effect of a fall in wage rates really were a reduction in total wage payments and consumer spending, the rate of profit would rise all the more, for all that this effect would really mean would be a shift of sales revenues from the sellers of consumers' goods to the sellers of capital goods, and, at the same time, a reduction in aggregate costs.

Critique of the “Paradox-of-Thrift” Doctrine

Another popular Keynesian doctrine that calls for special attention is the alleged “paradox of thrift.” According to this doctrine, the more people attempt to save, the poorer they become. Instead of being a principal foundation of economic progress and prosperity, saving is made to appear as the cause of unemployment and poverty. Samuelson, a leading supporter of this doctrine, states it as follows:

In a multiplier model with unchanged investment, an upward shift in the savings function, reflecting an increase in thriftiness, will actually reduce income and output. How much? Output is reduced in a multiplied way until income falls low enough to bring people's new desired saving again into equality with investment. Thus an attempt to save more may lead, instead, to a lower income and no more saving or investment.

Just when we have learned Poor Richard's wisdom, along comes a new generation of financial wizards who claim that in depressed times the old virtues may be modern sins.⁴⁵

Now the paradox-of-thrift doctrine rests entirely on the central notion of the Keynesian analysis that there is room in the economic system for only a strictly limited amount of profitable investment. It is only on this basis that the attempt to save a larger proportion of income

implies the necessity of a smaller amount of income. Thus, for example, if there were room in the economic system for only one unit of saving that could be profitably invested, and people sought to save only 1 percent of their income, their income could be 100 and still be consistent with the allegedly limited profitable opportunities for investment. If, however, they seek to save 20 percent of their income, then their income can be no more than a mere 5 and still be consistent with the allegedly limited profitable opportunities for investment.

It should be apparent that the paradox-of-thrift doctrine is utterly absurd. In the context to which it is meant to apply most strongly—namely, that of depression and mass unemployment—saving and investment, far from being at any kind of maximum limit, are extremely low or even negative, as we saw just a few pages ago. And, as we saw even more recently, it is precisely when saving and investment are restored, as the result of a fall in wage rates, unit costs of production, and prices, that the rate of profit is restored, along with full employment.

At all other times, as I have shown, there is room for far more profitable investment in the economic system than the power of saving can ever have the capacity to meet. One need only recall the enormous extent of the need for additional capital in its various forms, the extent of the need for savings to finance housing, and the fact that the downtown real estate of a single city all by itself provides an investment outlet for a virtually infinite amount of savings. At the same time, one should recall that the effect of a higher degree of capital intensiveness in the economic system is a more rapid rate of economic progress, including, as a by-product, a more rapid rate of increase in the quantity of commodity money and thus the corresponding addition of a positive monetary/net-investment component to the rate of return.⁴⁶ On the basis of these facts, it follows that in the absence of financial contraction caused by preceding inflation and credit expansion, the rate of return on capital can be assumed to be not only positive but sufficiently positive to make investment worthwhile for more savings and capital than people are capable of accumulating. And finally, as I have shown, to whatever extent people do or might for any reason decide to accumulate savings in the form of cash, that very fact operates further to raise the rate of return on capital.⁴⁷

The Keynesians' preoccupation with the utterly fictitious problem of saving as a cause of poverty bears major responsibility for the very real problem of growing poverty as the result of a lack of saving. Based on their hostile economic analysis of saving, the Keynesians have brought about the enactment of correspondingly hostile government economic policies toward saving. The result has been economic stagnation and decline, whose nature and

significance are captured in the words: *the rust belt*. Over a span of approximately two generations, the intellectual rot of Keynesianism has helped to bring about the physical rot of the industrial heartland of the United States.⁴⁸

Critique of the Saving Function

The errors of the Keynesian analysis in connection with saving include its very promulgation of the "saving function." There is no such thing as saving being a mathematical function of income. Saving out of income continues to exist only because incomes continue to grow, as the result of an increase in the quantity of money. As I have shown, if the quantity of money stopped growing, saving out of income would come to an end, once accumulated savings and capital reached a sufficient height relative to income.⁴⁹ Nor, as I have shown, is there any actual tendency for saving to constitute a rising share of income as income rises. The appearance of such a tendency is entirely the result of the fact that high incomes largely overlap with incomes that are saved heavily for different reasons, notably high incomes constituted by high rates of profit and high incomes that are considered transitory by their recipients.⁵⁰

In connection with saving as a continuing phenomenon, it should be recalled once more that the same cause that brings this about, namely, the continuing increase in the quantity of money and volume of spending in the economic system, adds correspondingly to the average rate of profit and interest. Indeed, most of the saving that goes on in the economic system takes place precisely out of this elevated rate of return on capital.⁵¹ This fact, of course, adds still a further perspective on the errors of Keynesianism with respect to saving and its relationship to the rate of return.

Critique of the "Liquidity-Preference" Doctrine

The final aspect of the Keynesian analysis that must be considered is the "liquidity-preference" doctrine. Liquidity preference or, as Hazlitt aptly describes it, "cash preference," is what is supposedly responsible for the existence of a minimum, irreducible rate of return below which lenders and investors will not lend or invest.⁵² They will allegedly not lend or invest below a 2 percent rate of return because they would prefer to hold cash instead.

Now, on the basis of all that I have established concerning the rate of return, it is virtually certain that in the absence of inflation and credit expansion and the subsequent financial contraction that results, the rate of return would actually be substantially in excess of 2 percent. But even if it were not, and even if that fact resulted in a tendency toward holding savings in the form of cash, the very existence of that tendency would itself operate to

raise the rate of return, as I showed in the last chapter.⁵³

In addition to this, it is also necessary to question the assumption that a 2 percent rate of return is the minimum at which people are willing to lend or invest. For if for some reason it did become necessary for the economic system to operate with a rate of return below 2 percent, there would be nothing to prevent it from doing so.⁵⁴

The Keynesians advance two arguments that attempt to show why 2 percent, or a rate not far from 2 percent, constitutes the practical lower limit to the rate of return lenders and investors will accept. In the words of Keynes himself:

We have assumed so far an institutional factor which prevents the rate of interest from being negative, in the shape of money which has negligible carrying costs. In fact, however, institutional and psychological factors are present which set a limit much above zero to the practicable decline in the rate of interest. In particular the costs of bringing borrowers and lenders together and uncertainty as to the future of the rate of interest . . . set a lower limit, which in the present circumstances may be as high as 2 or 2½ per cent. on long term.⁵⁵

The uncertainty as to the future of the rate of interest that Keynes refers to is the fear that it may rise from its present level and thus create a capital loss for any investor who finds it necessary to sell his investment—for example, a long-term bondholder who buys a bond when interest rates are 2 percent, and must sell it when interest rates rise to 4 percent, and who thus suffers a capital loss.⁵⁶

Now neither of these arguments in fact supports the conclusion that people are unwilling to lend or invest below some arbitrary rate of return. At most, they support the conclusion that at lower rates of return, the demand for money for holding will be somewhat higher than at higher rates of return, and thus that the velocity of circulation of money will be somewhat lower and wage rates and prices will have to be somewhat lower in order to have full employment. The fact that there are costs of bringing lenders and borrowers together, and of otherwise investing, is always true. The existence of such costs merely requires that in order for lending and investing to be worthwhile, the size of the loan or investment, and the period of time for which it is made, be of some minimum.

For example, as we saw in Chapter 12, if the cost of making a given type of loan or investment were some minimum amount, such as \$100, then at a 2 percent annual interest rate it would not pay to lend any sum smaller than \$250,000 for a period as short as one week, because that would be the sum required to yield the minimum of \$100 in just one week at that annual rate of interest.⁵⁷ But it would certainly pay to lend smaller sums for longer periods of time, such as \$100,000, or

even \$50,000, for a year. And, in fact, when the pooling of small sums is allowed for, as is accomplished every day by such institutions as savings banks, the sums which it pays to lend and invest even at a rate of return as low as 2 percent, turn out to be far less than \$50,000 and for periods far shorter than a year. Indeed, even at a 1 percent annual rate of return and need for a \$100 minimum amount of interest, it would still pay to deposit a sum as small as \$10,000 for a period as short as a year.

The argument about uncertainty concerning the future of the rate of interest does not fare any better. If the rate of return on capital is extremely low and people hesitate to lend or invest for fear that it will rise, then either they are right in expecting the rate of return to rise, or they are wrong. If they are right, then the rate of return rises, and the alleged problem of too low a rate of return simply disappears. If they are wrong, and the rate of return does not rise, then there is no actual reason to fear the rise and they can lend and invest at the low rate of return. Indeed, if we consider the phenomenon of a rise in the rate of return on capital as such, rather than merely a rise in the rate of interest on loans, and keep in mind that what brings it about in the circumstances of recovery from a depression—namely, a recovery of productive expenditure and sales revenues—then it becomes clear that people have good reason to go ahead and invest immediately if they expect the rate of return to rise. This is because if they invest as stockholders or other categories of equity owners, they will actually *gain* from the rise in the rate of return. And if they do not expect the rate of return to rise, then they have no good reason to abstain from investing out of any fear of securities prices falling.

The liquidity-preference doctrine represents a profoundly wrong explanation of the rate of interest. According to Keynes, the rate of interest is “the reward for parting with liquidity, is a measure of the unwillingness of those who possess money to part with their liquid control over it. . . . It is the ‘price’ which equilibrates the desire to hold wealth in the form of cash with the available quantity of cash”⁵⁸ And, says Keynes, “If this explanation is correct, the quantity of money is the other factor, which, in conjunction with liquidity preference, determines the actual rate of interest in given circumstances.”⁵⁹

Thus, Keynes’s doctrine here is that the rate of interest is determined by the combination of “liquidity preference” and the quantity of money. And on this basis, he comes to the conclusion that if it is not already at its minimum acceptable level, the rate of interest can be reduced by the mere increase in the quantity of money, if not to zero, then at least to its minimum acceptable level.⁶⁰ And he further concludes that by means of reduc-

ing the rate of interest in such conditions, namely, where it is not yet at its minimum acceptable level, the increase in the quantity of money will serve to make possible an expansion in employment and production, a result of which will be a reduction in the “marginal efficiency of capital”—i.e., the rate of profit.⁶¹

Now the fact is that “liquidity preference” is not at all a determinant of the rate of interest, much less of the rate of profit. This is dramatically illustrated by conditions under rapid inflation, where the desire to hold money virtually disappears and the rate of interest, instead of approaching zero, as the liquidity-preference doctrine implies, rises to extremely high levels. By the same token, the less rapidly the supply of money increases and the correspondingly greater is the desire to hold money, the lower is the rate of interest, not the higher—again, in contradiction of what the liquidity-preference doctrine implies.

As we have seen, the rate of interest is governed by the rate of profit, not vice versa; and the more rapidly the quantity of money is increased, the higher tends to be the rate of profit and thus the higher tends to be the rate of interest.⁶² The rise in prices that results from an increasing quantity of money also contributes to the rise in interest rates, in that it brings about increases in the demand for loanable funds to buy goods such as houses, land, and raw materials in the face of prospective higher prices for them. In the absence of higher interest rates, the purchase of such goods would become progressively more profitable, the more rapidly the quantity of money increased and prices rose. Interest rates must rise in the face of increases in the quantity of money, in order to limit the increase in demand for loanable funds that would otherwise result both from a higher rate of profit and, as far as they are present, rising commodity prices. As I have shown, because the increase in the quantity of money and consequent rise in spending increases the rate of profit and makes prices rise, it is impossible lastingly to reduce, let alone eliminate, the rate of interest by means of increasing the quantity of money. If carried out consistently, such an attempt would entail the continual acceleration of the increase in the quantity of money and thus the ultimate destruction of the monetary system. It would not eliminate or even lastingly hold down the rate of interest.⁶³

It should not be necessary to repeat here the critique I have made of the closely associated error of thinking of the rate of interest as the price of money, which Keynes does when he describes the rate of interest as “the ‘price’ which equilibrates the desire to hold wealth in the form of cash with the available quantity of cash . . .”⁶⁴ Interest is not the price of money, but the difference between the money borrowed and the money repaid, which dif-

ference tends to be the greater the more rapidly the quantity of money increases between the time of borrowing and the time of repayment.

The critique of the liquidity-preference doctrine can be combined with a further critique of Keynes’s doctrines concerning consumption, saving, employment, and the rate of profit. We have seen that the problem of unemployment, according to Keynes, rests on the fact that people insist on saving. If they did not save, if they only consumed, the “multiplier” would allegedly be infinite, and full employment would exist.

It is instructive to examine Keynes’s doctrines precisely in conditions in which there would be no saving whatever—no net saving out of income and no gross saving out of sales revenues. Such conditions would be similar to those which characterized Adam Smith’s “early and rude state of society” and Marx’s “C–M–C” sequence, but go beyond them in that there would not even be saving in the form of cash holdings, because everyone would race to consume immediately.⁶⁵

In such conditions, not only would there be no saving, but also there would be no liquidity preference. In such conditions, according to Keynes, because there is no saving, employment must be full; and because there is no liquidity preference, the rate of interest and profit must be zero. Yet in fact, in such conditions, employment would be virtually zero and the rate of profit and interest would be infinite. This is because there would be no demand for labor in the production of products for sale, and while sales revenues would exist, there would be no productive expenditure and thus no costs to deduct from sales revenues, and there would be no capital. Thus, profits would equal the whole of sales revenues and, when divided by zero of capital invested, would yield an infinite rate of return.⁶⁶

4. The Economic Consequences of Keynesianism

As I have shown, the essential economic policy advocated by Keynesianism is government budget deficits, which are held to be necessary to prevent or combat mass unemployment. This is the essence of “fiscal policy.” Thus, it should be obvious that matters are misrepresented when fiscal policy is presented as some kind of neutral tool which now must be used to expand the economy, and now to slow it down. The underlying economic problem according to the Keynesians is mass unemployment, and that requires a continuously expansionary policy, which is believed to be budget deficits. At most, the Keynesians may be prepared to call for a reduction in the size of the deficit if the expansion in spending allegedly induced by it is greater than necessary

to achieve full employment and is thus held to contribute to rising prices. In virtually no circumstances does the logic of their position permit them to call for budget surpluses.

The most effective method of achieving a budget deficit according to the Keynesians is by increasing government spending rather than by reducing taxes. This is because, as we have seen, the so-called government-spending multiplier is held to be one larger than the multiplier allegedly associated with a reduction in taxes and is therefore believed to be correspondingly more “stimulative.”⁶⁷

The increase in government spending is held to be truly wonderful. It is alleged to be not only costless but also the source of a substantial increase in real income over and above itself. It is held to be the means of absorbing the allegedly destructive additional savings that accompany full employment and thus of permitting people to benefit from all of the additional output that full employment brings over and above their additional saving. The savings the government takes allegedly costs people nothing because those savings supposedly could not even be formed in the absence of the government’s willingness to take them. And, say the Keynesians, people are then able to keep for themselves all that their additional employment produces over and above those additional savings. Thus, not only is there a free lunch for the government and its clients, but also, the Keynesians believe, the government’s willingness to enjoy its free lunch is the necessary basis for the producers being able to produce and enjoy most of their additional product. Thus Keynesianism is consumptionism *par excellence*. For no doctrine is more adept in claiming that parasitism is a source of actual enrichment to its victims.

As I have pointed out repeatedly, Keynesianism is the philosophy which holds that “pyramid-building, earthquakes, and even wars may serve to increase wealth.”⁶⁸ With this philosophy as a starting point, there is almost no program a government could adopt that would not represent a significant improvement in comparison, since it could almost certainly be designed so that at least some people would directly benefit from it. Public housing, public transportation, public education, socialized medicine, and so forth all compare favorably with pyramid building, earthquakes, and wars in terms of their ability to provide benefits to at least some people for some period of time.

The Growth in Government

An inevitable effect of the influence of such ideas is the increase in the size and scope of government activity. As James Mill observed in criticizing very similar ideas in the early nineteenth century:

Were the exhortations to consumption . . . addressed only to individuals, we might listen to them with a great deal of indifference; as we might trust with abundant confidence that the disposition in mankind to save and to better their condition would easily prevail over any speculative opinion, and be even little affected by its practical influence. When the same advice, however, is offered to government, the case is widely and awfully changed. Here the disposition is not to save but to expend. The tendency in national affairs to improve, by the disposition in individuals to save and to better their condition, here finds its chief counteraction. Here all the most obvious motives, the motives calculated to operate upon the greater part of mankind, urge to expence; and human wisdom has not yet devised adequate checks to confine within the just bounds this universal propensity. Let us consider then what are likely to be the consequences should this strong disposition become impelled, and precipitated by a prevailing sentiment among mankind. One of the most powerful restraints upon the prodigal inclinations of governments, is the condemnation with which expence, at least beyond the received ideas of propriety, is sure to be viewed by the people. But should this restraint be taken off, should the disposition of government to spend become heated by an opinion that it is right to spend, and should this be still farther inflamed by the assurance that it will by the people also be deemed right in their government to expend, no bounds would then be set to the consumption of the annual produce. Such a delusion could not certainly last long; but even its partial operation, and that but for a short time, might be productive of the most baneful consequences.⁶⁹

Just as James Mill anticipated, the success of the kind of ideas advocated by Keynes in gaining popular influence has indeed been followed by the most baneful consequences. Among them is an approximately fourfold increase in the relative size of government spending in the United States. Between 1929 and the present day, government spending has increased from approximately 11 percent of “national income” to approximately 40 percent. This has meant a corresponding decline in the freedom of the individual to spend his own income as he chooses and the imposition of a reign of fear of the tax authorities, as the measures taken by the government to obtain the growing percentage of income have become more and more severe. It has also meant a vast increase in the government’s interference in the daily lives of the people in countless other ways as well, which are financed with the government’s additional funds. And, of course, there have been other highly destructive consequences stemming from individuals’ loss of control over their incomes and the accompanying growth in government regulation, most notably, the undermining of capital accumulation and economic progress.

Budget Deficits, Inflation, and Deflation

Although Keynesianism is, and must be, radically

opposed to the quantity theory of money, for the reasons explained at the beginning of this chapter, it nevertheless recognizes the need to couple its policy of budget deficits with an expansion in the quantity of money. This is because even though Keynesianism avows that what increases spending is the mere existence of budget deficits, the fact is that in the absence of substantial increases in the quantity of money, a policy of sustained large-scale budget deficits would inevitably result in the government's bankruptcy.

Bankruptcy would be the result because the government's accumulated debt would continue to grow and the burden of servicing the debt would come to require more and more revenue. Increases in taxes would at most only delay the government's bankruptcy. For they would reduce the country's ability to produce and to compete internationally (as does, of course, the government's absorption of savings when it borrows to finance its deficits). The government's tax revenues would thus be unable to keep pace with its growing financial obligations caused by the deficits. The rate of interest the government had to pay on its debt would rise. Eventually the day would come when the government had to repay a portion of its debt and found itself unable to borrow the means of doing so. At that point, it would be bankrupt in the literal sense of the term.

The fact that in the absence of the ability to create money, a policy of budget deficits leads to a country's economic and financial decline and the government's bankruptcy, means that in such circumstances a policy of deficits is actually *deflationary*! This is the case under any kind of meaningful gold standard. Under a gold standard, a policy of deficits has the effect of reducing the supply of gold that circulates within a country's borders. This is because in undermining capital accumulation in the country, the effect of the deficits is to reduce the country's share of world commerce and thus the share of the world's gold that it possesses.⁷⁰ Within the country, moreover, the threat of the government's bankruptcy, and its attendant uncertainties, must lead to a greater demand for the holding of gold as opposed to productive expenditure and investment. Furthermore, insofar as the monetary system of the country may use government debt as an asset standing behind the issuance of fiduciary media, the quantity of money in the country is further threatened. For any threat to the solvency of the government in such circumstances is a threat to the solvency of the banks that hold its securities as an asset. Thus, under a meaningful gold standard, a policy of deficits could not achieve the Keynesian objective of expanding spending, but would sooner or later accomplish the exact opposite.⁷¹

Although they never acknowledge the existence of conditions in which deficits would be deflationary, the

Keynesians nevertheless seem to know very well that such conditions would exist under any real gold standard. And thus, to a man, they are totally opposed to the gold standard, which they do everything possible to ridicule. They oppose the gold standard because they know that if the policy of deficits is in fact to succeed in increasing total spending, the deficits must largely be financed by an increase in the quantity of money and that the government must have the power to bring about this increase. A gold standard, on the other hand, deprives the government of this power. It makes the increase in the quantity of money depend on the increase in the supply of gold.

The Keynesians' advocacy of a policy of budget deficits is an implicit advocacy of inflation. In addition, the Keynesians explicitly advocate inflation, in the form of credit expansion, insofar as they believe that it can succeed in reducing the rate of interest—that is, insofar as the rate of interest is not yet at its allegedly irreducible level of approximately 2 percent.

As Chapter 12 has shown, and as the next chapter will show more fully, the creation of money by the government, or with the encouragement of the government, is the essence of the inflation problem—inflation is the government's creation, or sponsorship of the creation, of money at a rate more rapid than the increase in the supply of the precious metals. And Keynesianism bears primary responsibility for it in the countries of the Western world today and since the 1930s.

Keynesianism and Economic Destruction

Thus, in appraising the consequences of the Keynesian policies, it is necessary to charge them with all the destructive consequences of inflation. This includes rising prices and the impoverishment of everyone whose income or assets are contractually fixed in terms of a definite sum of money. It includes the arbitrary redistribution of wealth and income from creditors to debtors and from those who receive the new money relatively late to those who receive it relatively early. It includes—as does a policy of deficits without resort to inflation—the impairment of capital formation and thus of the rise in the productivity of labor and real wages. Indeed, if carried out on a large enough scale, capital decumulation and an actual fall in the productivity of labor and real wages are the result.⁷²

I have said that Keynesianism and its hostility to saving are responsible for the vast economic devastation conveyed in the words “the rust belt.” This devastation has occurred because under the influence of Keynesianism literally several trillion dollars of savings have been absorbed in government budget deficits—an amount of savings equal to the growth in the publicly held national debt in the years since the time of Keynes.⁷³ Over this

period, confiscatory taxation applied to large personal incomes and to corporate profits, capital gains, and inheritances have prevented trillions more of savings from being made in the first place or, in the case of inheritance taxes, being kept. Such taxation has been strongly supported by Keynesianism, precisely because the taxes fall on saving. As we shall see, inflation too, like inheritance taxes, destroys savings already accumulated, and does so on a vast scale.

Thus factories, machinery, stocks of materials and supplies, power plants, railroads, bridges, tunnels, and homes that these savings and potential savings would have made possible have not come into existence because the necessary savings have been diverted into financing the government's budget deficits, have been prevented from occurring in the first place, or have been prevented from being maintained. The result has been a sharp decline in the rate of economic progress in the United States, if not outright economic stagnation, and increasing difficulty in replacing existing capital assets when they wear out.

In connection with this last, under conditions even of modest increase in the overall supply of capital goods—let alone stagnation or outright capital decumulation—the very fact of the economic development of new areas, such as the U.S. Far West, implies the economic decline of older areas. This is the case because in such conditions additional capital for the one, or at least additional capital for the one over and above any modest increase in the total of capital, can be obtained only by failing to provide replacement capital for the other.

Ironically, as we shall see, a further consequence of the inflation inspired by Keynesianism is a wiping out of the real rate of return on capital and the creation of conditions in which people actually do find it necessary to hoard their savings—not, to be sure, in the form of depreciating paper money, but in the form of physical assets whose price can rise, above all, gold and silver.⁷⁴ Inflation ultimately destroys the private granting of credit calling for repayment in paper money, and makes impossible the writing of contracts of any kind which are stated in terms of a fixed sum of money. For a variety of reasons it has an inherent tendency to go on accelerating until the point is reached at which paper money ceases to be acceptable in commerce. At that point, if the government has prevented the development of a new money that the market would create in the form of gold and silver, inflation actually succeeds in the destruction of money altogether, and with it, of an indispensable foundation of a division-of-labor society. Along the way, inflation creates the potential for a major depression, which is actualized if the inflation is stopped, sharply slowed, or, indeed, even fails to accelerate sufficiently.⁷⁵

Finally, it must be kept in mind that inflation is responsible for the imposition of wage and price controls, which are enacted in misguided efforts to stop it. As I showed in Chapters 7 and 8, wage and price controls create economic chaos and culminate in a totalitarian socialist dictatorship and economic collapse.

Thus, Keynesianism and the policies it gives rise to have played a leading and essential role in causing the economic decline of the United States that has become visible over the last generation and which is likely to continue. Keynesianism is a consistent assault on the foundations of prosperity: it is antisaving, antigold, anti-balanced budgets, antilimited government. Ironically, what it is not anti is unemployment. It is *not* the solution for unemployment.

Why Keynesianism Is Not a Full-Employment Policy

The Keynesian policies of deficits and inflation are not only not necessary for the achievement of full employment, but *do not achieve it*. Indeed, deficits by themselves, apart from the creation of money, actually cause more unemployment, both because of their deflationary effects, explained above, and because in depriving business of capital funds, they reduce the ability of business to make productive expenditures and thus to pay wages. And, as I explained in Chapter 13, even when the deficits are combined with inflation of the money supply, much, most, or even all of the extra spending that takes place can be nullified by wage increases that are just as rapid or even more rapid, with the result that little or no additional employment is actually achieved.⁷⁶ Furthermore, as I also explained in Chapter 13, much of any additional employment that might be achieved is likely to be of little or no economic value to those whose production must pay for it, because of the inherent nature of the output of those reemployed in connection with government make-work projects.⁷⁷ Finally, the inflation and credit expansion Keynesianism leads to, and the artificial elevation of the velocity of circulation and stimulus to indebtedness that result, help to create a constant potential for renewed depression and mass unemployment.

As I have shown, what brought about full employment in World War II was not the Keynesian policies of deficits and inflation by themselves but their coupling with wage and price controls. It was this which finally established a relationship between wage rates and prices, on the one side, and the quantity of money and volume of spending, on the other, that enabled the volume of spending for goods and labor to buy all that was offered.⁷⁸ Of course, this same result could have been achieved by a free market in labor, without any of the loss of output (not to mention human life) that took place on the battlefields of

the war and without any of the shortages and economic chaos caused by wage and price controls. Thus, even when applied in combination with wage and price controls, Keynesianism should not be thought of as a full-employment policy, but as the policy that succeeds in destroying the economic value of full employment.

Keynesianism Versus the Rate of Profit: “The Euthanasia of the Rentier” and “The Socialization of Investment”

Keynesianism’s concern with the alleged lowness of the rate of profit at the point of full employment turns out to be nothing but a shedding of crocodile tears. As I have said, the effect of its policies is to wipe out the real rate of return on capital and actually to cause the very hoarding of savings it claims to fear. To discover how Keynesianism accomplishes this, it is not necessary to wait until the discussion of inflation in the next chapter. The fact that the Keynesian policies reduce the real rate of return on capital is implied precisely in its attempt to neutralize current savings, either by absorbing them in budget deficits that will never be repaid or by seizing them outright through taxation. The savings that are taken away, by these or any other methods, for the most part *come out of the rate of return*. They are the result of saving specifically out of profit and interest incomes. Thus, taking them away is tantamount to taking away part of the rate of return itself. For taking away savings means, at the same time, taking away the profits and interest that are the source of the savings.

The Keynesian policies are dishonest. Even if the Keynesian analysis were correct, which it certainly is not, the question would have to be asked of why it does not consider trying to raise the effective rate of return by reducing taxes on profits and interest? Only after all taxes on profits and interest had been eliminated, would it be legitimate to talk of a problem of too low a rate of return in the economic system.

The fact is, that when all is said and done, it turns out that Keynesianism *is really not concerned with any alleged insufficiency of the rate of return*. That is merely a convoluted pretext for more government intervention. Its actual belief, expressed by Keynes in the final chapter of *The General Theory*, is that the rate of return is *too high!* If this is difficult to believe in view of the diminishing-marginal-efficiency-of-capital and unemployment-equilibrium doctrines, which are the core of his book and of the whole Keynesian analysis, consider the following passages, which are in Keynes’s own words. They begin with an implicit reference to the alleged paradox-of-thrift doctrine and with an expression of satisfaction that on the basis of that doctrine his analysis allegedly deprives great inequality of wealth of one of its “chief social justifications.”

Thus our argument leads towards the conclusion that in contemporary conditions the growth of wealth, so far from being dependent on the abstinence of the rich, as is commonly supposed, is more likely to be impeded by it. One of the chief social justifications of great inequality of wealth is, therefore, removed. I am not saying that there are no other reasons, unaffected by our theory, capable of justifying some measure of inequality in some circumstances. But it does dispose of the most important of the reasons why hitherto we have thought it prudent to move carefully. . . .

For my own part, I believe that there is social and psychological justification for significant inequalities of incomes and wealth, but not for such large disparities as exist to-day. . . . Much lower stakes will serve the purpose equally well, as soon as the players are accustomed to them.⁷⁹

On the next three pages Keynes goes on with his newly revealed theme that profits are actually too high under capitalism. He even adopts a style of language which sounds hardly distinguishable from Marxism:

I feel sure that the demand for capital is strictly limited in the sense that it would not be difficult to increase the stock of capital up to a point where its marginal efficiency had fallen to a very low figure. . . .

Now, though this state of affairs would be quite compatible with some measure of individualism, yet it would mean *the euthanasia of the rentier, and, consequently, the euthanasia of the cumulative oppressive power of the capitalist to exploit the scarcity-value of capital*. . . .

I see, therefore, the rentier aspect of capitalism as a transitional phase which will disappear when it has done its work. And with the disappearance of its rentier aspect much else in it besides will suffer a sea-change. It will be, moreover, a great advantage of the order of events which I am advocating, that the euthanasia of the rentier, of the functionless investor, will be nothing sudden, merely a gradual but prolonged continuance of what we have seen recently in Great Britain, and will need no revolution.

Thus we might aim in practice (there being nothing in this which is unattainable) at an increase in the volume of capital until it ceases to be scarce, so that the functionless investor will no longer receive a bonus; and at a scheme of direct taxation which allows the intelligence and determination and executive skill of the financier, the entrepreneur *et hoc genus omne* [translation: and all of this genus] (who are certainly so fond of their craft that their labour could be obtained much cheaper than at present), to be harnessed to the service of the community on reasonable terms of reward.⁸⁰

In other words, Keynes sees the effect of his policies as that of accomplishing the just demands of Marxism—the expropriation of the “expropriators” and the redistribution of their allegedly excessive and ill-gotten wealth to the state and the population at large—but without the necessity of a violent revolution.

Not surprisingly he advocates *the socialization of investment*: “Furthermore, it seems unlikely that the influence of banking policy on the rate of interest will be sufficient by itself to determine an optimum rate of investment. I conceive, therefore, that a somewhat comprehensive socialisation of investment will prove the only means of securing an approximation to full employment.”⁸¹

The meaning of this last passage is that Keynes thinks it unlikely that an increase in the quantity of money (which is what he means by “banking policy”) will be sufficient by itself to drive the rate of return below 2 percent, and that investment by the government, which will be willing to invest at a rate of return below 2 percent, will be necessary. Keynes claims to believe that nothing momentous is involved in the socialization of investment, for he immediately adds the words: “But beyond this no obvious case is made out for a system of State Socialism which would embrace most of the economic life of the community.”⁸² These words in turn are quickly followed by the admission: “Moreover, the necessary measures of socialisation can be introduced gradually and without a break in the general traditions of society.”⁸³ It should be obvious, of course, that since the total of all the capital that is accumulated is nothing but the summation of the investments of the preceding years, full socialism requires nothing more than the socialization of new investment plus the lapse of time. Nevertheless, incredibly, Keynes is touted as a man who saved capitalism.

Keynes’s views in the above passages are so confused that it may well be the case that he believed 2 percent was simultaneously an excessively high rate of return, providing unnecessarily high stakes to the “players,” and too low a rate of return. Or, when he complained of the rate of return being too high, he may simply have forgot-

ten his arguments about the rate of return being too low, or perhaps he never took them very seriously in the first place. The following statement, taken from the middle of his book, appears to support this latter view:

There is the possibility, for the reasons discussed above, that, after the rate of interest has fallen to a certain level, liquidity preference may become virtually absolute in the sense that almost everyone prefers cash to holding a debt which yields so low a rate of interest. In this event the monetary authority would have lost effective control over the rate of interest. But whilst this limiting case *might become practically important in the future, I know of no example of it hitherto.*⁸⁴

The inescapable implication of these words is that Keynes knows no actual example of the existence of an *unemployment equilibrium* and that his entire doctrine is purely in the realm of the hypothetical. For if the rate of interest is not actually at its alleged minimum acceptable level, Keynes has no grounds, even on his own terms, of asserting the existence of an unemployment equilibrium.

Thus, it appears that Keynes’s actual objections to capitalism may well have been based merely on the standard resentments against inequality and the alleged injustice of the existence of profit and interest, and that his doctrine was merely an added pretext for government intervention. The government must intervene because the rate of profit is too high, and, if that objection does not gain sufficient support, then because the rate of profit is too low, which is the argument of the body of Keynes’s analysis. In any case, the government must intervene and seize more power. Any argument that serves will do. And thus Keynesianism ends exactly where it began: a piece of flotsam and jetsam from the wreckage of critical thought that is carried along by the tide of irrationalism and anticapitalism.

17. Cf. above, Fig. 13–1, on p. 545. Also cf. McKenna, p. 281, for a standard Keynesian textbook presentation of the diagram.

18. The fallaciousness of the union argument is recognized by Gardner Ackley in his *Macroeconomic Theory* (New York: The Macmillan Company, 1961), pp. 388–389.

19. Later in this chapter, I show that to the extent that in consequence of a fall in wage rates the demand for capital goods is increased at the expense of the demand for labor, the rate of profit would be correspondingly increased, and would be increased even if an actual decrease in the demand for labor and consumers' goods resulted. See below, p. 884.

20. Cf. McKenna, p. 210. Also cf. Ackley, p. 369.

21. Cf. McKenna, p. 210.

22. See McKenna, pp. 216–220.

23. Cf. *ibid.*, p. 219.

24. See above, Fig. 13–1, on p. 545.

25. Cf. McKenna, pp. 216–217.

26. Keynes, *General Theory*, pp. 261–262. Italics in the last sentence are supplied.

27. Another passage from Keynes that provides conclusive support for my exposition of his views is this one, which appears earlier in *The General Theory*: “. . . the position of equilibrium, under conditions of *laissez-faire*, will be one in which employment is low enough and the standard of living sufficiently miserable to bring savings to zero. . . . Assuming correct foresight, the equilibrium stock of capital . . . will, of course, be a smaller stock than would correspond to full employment of the available labour; for it will be the equipment which corresponds to that proportion of unemployment which ensures zero saving. *Ibid.*, pp. 217–218.

28. *Ibid.*, p. 136.

29. Cf. Ackley, pp. 465–466.

30. Ackley believes he advances a different basis for the alleged declining yields to net investment when he cites the factor of increasing capital intensiveness and the adoption of more round-about methods of production in the sense used by Böhm-Bawerk. See Ackley, pp. 466–472. Actually, this factor is fully in the spirit of the law of diminishing returns. Indeed, the basis for claiming diminishing returns is precisely the increasing degree of capital intensiveness.

31. See above, pp. 76–91 *passim*.

32. See *The Ayn Rand Lexicon*, Harry Binswanger, ed. (New York: New American Library, 1986), pp. 104–105.

33. Cf. Paul Samuelson and William Nordhaus, *Economics*, 13th ed. (New York: McGraw Hill Book Company, 1989), pp. 66–67.

34. In reality, of course, it is an error to conceive of net investment as an actual expenditure. As we know, rather than being an expenditure, net investment is in fact the *difference* between productive expenditure, which is the actual expenditure present, and business costs, which are largely an accounting abstraction, based on the productive expenditures of previous accounting periods. On this point, see above, pp. 702–705.

35. This latter possibility should not be dismissed in view of the blatant absurdities the Keynesians have embraced, and which cannot be explained on the basis of any kind of intellec-

tual confusion. Keynes's endorsement of wars, earthquakes, and pyramid building as sources of prosperity are the leading example. See Keynes, *General Theory*, pp. 129–131.

36. The saving referred to is, of course, saving out of net income, i.e., net saving.

37. See U.S. Department of Commerce, Office of Business Economics, *National Income 1954 Edition, A Supplement to the Survey of Current Business* (Washington, D. C.: U.S. Government Printing Office, 1954). Data for saving appear on page 164 of this document; data for net investment are derived by subtracting capital consumption allowances, reported on page 164, from gross private domestic investment, which is reported on page 162.

38. See above, pp. 702–705.

39. See above, *ibid.*

40. Again, see above, *ibid.* See also above, pp. 723–725 and 744–750.

41. See, for example, the exposition of the multiplier in Samuelson, which was discussed above, on p. 690.

42. See above, pp. 707–708.

43. See above, pp. 589–590. See also Ludwig von Mises, *Human Action*, 3d ed. rev. (Chicago: Henry Regnery Co., 1966), pp. 568–569.

44. These conclusions are not significantly disturbed by the fact that a portion of the expenditure made on account of plant and equipment is itself in the form of wage payments—such as the payment of the wages of workers installing machinery and the wages of construction workers paid by firms that act as their own contractors. To the extent that cases of this kind exist, the reduction in total wage payments and the consumer spending it supports is less, and a portion of the reduction in aggregate costs is achieved by the fact that the new wage payments show up as depreciation cost over a long period of years rather than all at once.

45. Samuelson and Nordhaus, 13th ed., pp. 183–184.

46. On these points, see above, pp. 56–58, 744, and 838–856.

47. See above, pp. 837–838.

48. For elaboration, see below, pp. 889–890. See also below, pp. 930–937.

49. See above, pp. 758–759, 768–771, and 834–837.

50. See above, pp. 741–743.

51. See above, pp. 836–837.

52. See Henry Hazlitt, *The Failure of the “New Economics”* (New York: D. Van Nostrand & Co., 1959) p. 193.

53. See above, pp. 837–838.

54. While this might not be as easily established in the case of a negative or zero percent rate of return, the fact that as the rate of return approaches zero, land values approach infinity, implies all by itself that the rate of return must indeed always be positive at some significant level.

55. Keynes, *General Theory*, pp. 218–219.

56. *Ibid.*, pp. 201–202.

57. See above, pp. 521–522.

58. Keynes, *General Theory*, p. 167.

59. *Ibid.*, pp. 167–168.

60. *Ibid.*, p. 171.

61. Indeed, insofar as the rate of interest is not yet at its minimum acceptable level and thus has room to fall, and insofar as a fall in wage rates and prices increases the buying power of

a given stock of money and can thus be likened in its effects to an increase in the quantity of money, Keynes is prepared to concede that a fall in wage rates and prices can increase the volume of employment. This alleged concession is known as the “Keynes effect.” See *ibid.*, p. 261. See also McKenna, pp. 216–220.

62. Concerning the effect of increases in the quantity of money on the rate of profit, see above, pp. 762–774. For the connection to a higher rate of interest, see above, pp. 520–521.

63. Again, see above, pp. 520–521.

65. Concerning the views of Smith and Marx in this area, see above, pp. 475–480.

66. In 1959, I showed Henry Hazlitt an early, unpublished paper that presented some of my basic views on profit and interest and that concluded with these very points. Beginning with the third printing of *The Failure of the “New Economics,”* which appeared in the following year, he very graciously found space to describe these points and credit me for them. See, *ibid.*, p. 196.

67. See above, pp. 712–715.

68. Keynes, *General Theory*, p. 129.

69. James Mill, *Commerce Defended* (London, 1808), chap. 7; reprinted in *Selected Economic Writings of James Mill*, ed. Donald Winch (Chicago: University of Chicago Press, 1966), p. 140.

70. Depending on the relative size of the country’s economy, the by-product of a decline in its ability to produce, or of any lesser rate of increase in its ability to produce, is probably also to reduce the rate of increase in the world’s overall supply of gold, which, of course, depends on the ability to increase

production in general. This principle is operative even if the country itself does not possess gold mines. Gold mining outside the country will be negatively affected insofar as it depends directly or indirectly on what is produced within that country.

71. For a discussion of additional deflationary consequences of government budget deficits, see below, pp. 940–941.

72. For elaboration of all of these points, see below, pp. 925–938.

73. A significant fraction of the national debt is held by the Federal Reserve System and the banking system, as opposed to the general public. The increase in this portion of the debt represents the creation of new and additional money rather than the diversion of savings. Any lessening of the diversion of savings that this fact may appear to represent, is dwarfed by the vastly larger sums siphoned off under the social security system from savings into government consumption. Furthermore, as I have said, the creation of hundreds of billions of dollars of new and additional money is the essence of the problem of inflation and the root of all of the destructive consequences for capital accumulation that result from inflation.

CHAPTER 19

GOLD VERSUS INFLATION

PART A

INFLATION OF THE MONEY SUPPLY VERSUS ALTERNATIVE THEORIES OF RISING PRICES

1. The Analytical Framework of the Quantity Theory of Money

The quantity theory of money, as developed earlier in this book, shows that the cause of generally rising prices is an increase in the quantity of money. More specifically, it shows that the cause is an increase in the quantity of money at a rate *more rapid than the increase in the supply of gold and silver*. The increase in the supply of gold and silver, being itself a by-product of the general increase in the ability to produce, would show no tendency regularly or significantly to outstrip the increase in the supply of the mass of ordinary commodities, and to that extent would be incapable of causing a sustained significant rise in prices. In addition, since government intervention into the monetary system is what has been responsible for the quantity of money being able to increase more rapidly than the increase in the supply of gold and silver, the quantity theory of money implies that what is responsible for the problem of a persistent significant rise in prices is an increase in the quantity of money *caused by the government*.

Indeed, the quantity theory of money implies that inflation should be *defined* in terms of the increase in the

quantity of money—specifically, as an *increase in the quantity of money at a rate more rapid than the increase in the supply of gold and silver or, equivalently, as an increase in the quantity of money caused by the government*. Such a definition states the essential cause of the cluster of symptoms which people identify with inflation and which must be acted upon to eliminate those symptoms. It represents a definition in terms of fundamentals and provides, at the same time, a sound guide to corrective action. Nevertheless, the great majority of people today, including even the great majority of professional economists, define inflation in terms of one of its leading symptoms. They define it merely as *rising prices*.

The definition of inflation as rising prices says absolutely nothing about any specific cause of rising prices. It implies, therefore, that inflation can be caused by anything that raises prices.

Having accepted this definition, it is no wonder that people are confused about inflation. There are a vast number of things that might raise prices in one circumstance or another, ranging all the way from bad weather causing poor crops and thus higher farm-product prices to the development of a fad for some novelty. On the basis of the definition of inflation as rising prices, people are led to consider every possible cause of higher prices as a possible cause of inflation, and thus to believe that the cause of inflation can vary from case to case.

Thus, they believe that inflation can be caused, variously, either by “demand pull,” that is, by more spending outstripping the growth in the supply of goods and thus “pulling up their prices,” or by “cost push,” that is, by

rising costs forcing up prices. (The quantity theory of money is often thought to operate exclusively in the form of “demand pull” and is thus classified by many economists under the heading of “demand-pull inflation.”)¹

By “cost-push inflation” is meant, frequently but by no means always, the arbitrary demands of labor unions, which drive up wage rates and thus costs of production and prices. This variety of cost-push inflation is called “wage-push inflation.” In addition, there is supposed to be a second variety of cost-push inflation, namely, “profit-push inflation,” which allegedly occurs when the greed of businessmen is supposed to drive up the prices of critical raw materials, such as steel and cement, which in turn constitute costs of production to large numbers of other producers. The term profit-push inflation is also applied to cases in which the greed of businessmen selling consumers’ goods is supposed to drive up the prices of the consumers’ goods directly, without any rise in costs of production. (To incorporate this type of case, the term “sellers’ inflation” is sometimes used in place of “cost-push inflation.”)

Yet a third variety of cost-push or sellers’ inflation is supposed to exist in cases in which this or that crisis, such as the Arab oil embargo or the sale or giveaway of large quantities of wheat to the Soviet Union, disrupts the supply of one or more vital goods and so raises the costs of production of all the producers who require them. This species of cost-push inflation is sometimes termed “crisis-push inflation.”

Closely related to the doctrine of cost-push inflation is the doctrine of the “wage-price spiral.” According to this doctrine, prices rise because wages rise, and wages rise because prices rise. Wages and prices, it is believed, simply chase each other upward in a spiral, and that is why prices go on rising. (If a proponent of this doctrine is sympathetic to labor unions, he asserts that the process begins with an arbitrary rise in prices due to the profit-push of employers. If he is unsympathetic to labor unions, he asserts that it begins with an arbitrary rise in wages due to the wage-push of the unions.)

So-called demand-pull inflation is also supposed to take a variety of forms. In addition to being caused by an increase in the quantity of money, it is supposed to be capable of being caused by inexplicable increases in the velocity of circulation of money; by the unexplained existence of “inflation psychology”; by the growing use of credit cards, installment credit, or other forms of credit; and even by the sheer increasing greed of consumers for more goods.

The effect of believing that “inflation” can be caused by an extensive list of things that the mind has no clear-cut way of organizing or holding is that for all practical purposes people are led to regard inflation as

causeless. Ask the average person—or even many professors of economics—what causes inflation, and at most a blur of confused bits and pieces of knowledge about what might raise prices in this or that case comes to his mind. For all practical purposes he has absolutely no idea of the cause. For he believes that to determine the cause in the specific case at hand requires a special investigation, to determine which of all the various alleged possibilities is the actual explanation. On this basis, we can observe the appointment of successive panels of alleged experts to study the problem of inflation, as though the explanation had never been found.

But this is not the worst consequence of the definition of inflation as rising prices. For that definition not only opens the door to too-wide a range of possible explanations to be of any value. It also directly and powerfully suggests one particular, extremely simple explanation, which in fact is the most popular explanation—namely, that inflation is the result of the ill will of evil, powerful people: above all, of big businessmen driven by the greed for higher profits. This is necessarily the most popular explanation of inflation, given the general acceptance of its definition as “rising prices.”

This is because if inflation is defined simply as being rising prices, then it follows that inflation only comes into existence *when* businessmen raise their prices and *exists* only to the extent that they raise their prices. In other words, it follows from the current definition that inflation exists when and to the extent that someone—Jones, the corner grocer, General Motors, or whoever—raises his price. It follows further that inflation would not exist if Jones or whoever did not raise his price. In the absence of any clear-cut understanding of why Jones or whoever must raise his price, there is no way that people can avoid concluding that Jones or whoever is responsible for inflation.

The real view that most people have of inflation, therefore, is that it is something caused by the evil of private individuals, especially greedy businessmen.

This view of the nature of inflation suggests an apparent and seemingly logical remedy: the government, motivated by concern for the public welfare, should forbid the evil businessmen to raise their prices. Price controls, it appears, are the solution to inflation.

And just as inflation stands in people’s minds as a causeless phenomenon born of mere ill will, so price controls are regarded as having no effects but that of stamping out inflation. In the view of most people, what we have in the matter of inflation and price controls is a causeless evil overpowered by an otherwise effectless good. To put this another way, what most people do in the matter of inflation and price controls is to begin their thinking at the point of the businessman raising his

prices, and to end it at the point of the government entering the scene with a *Verbot*. All that comes before and all that follows after is a blank in their minds.

I have already explained both the effects of price controls and the actual cause of rising prices. My purpose here is to reinforce the quantity theory of money by refuting all of the other explanations of rising prices that have been advanced. I will show that all of the alternative explanations are either simply false or else, to the extent that they do contain some modest kernel of truth, constitute merely a further confirmation of the truth of the quantity theory of money. I will show that the increase in the quantity of money is not merely one possible cause of rising prices among many possible causes, but is *the universal cause of every sustained significant rise in prices*. At the conclusion of the first part of this chapter, it will be apparent, if it is not already, that as a means of furthering both our understanding and our ability to deal with the problem, inflation should not be defined as rising prices, but in terms of the universal underlying cause of rising prices. That is, to repeat, inflation should be defined either as an increase in the quantity of money at a rate more rapid than the increase in the supply of gold and silver or, equivalently, as an increase in the quantity of money caused by the government.

The Vital Demand/Supply Test for All Theories of Rising Prices

The equation, initially developed in Chapter 12, that

$$P = \frac{DC}{SC}$$

—i.e., the general consumer price level equals the aggregate demand (spending) to buy consumers' goods, divided by the aggregate supply of consumers' goods produced and sold—provides an indispensable conceptual framework for examining any possible explanation of rising prices and for confirming the truth of the explanation based on the quantity theory of money.

When people speak of inflation as a rise in prices, what they really have in mind is not an isolated rise in some prices here and there, offset by a fall in prices elsewhere, but a rise in the *generality* of prices. The general consumer price level is the weighted average of all consumer prices. As previously explained, the supply it reflects is the sum of all consumers' goods produced and sold, conceived of as so many units of an abstract consumers' good in general. This supply is purchased for a definite aggregate expenditure of money. The result is the general consumer price level.

The above equation, it must be recalled, shows the general consumer price level to be the resultant of a numerator, demand, divided by a denominator, supply.

The average price at which goods are sold is the spending to buy them divided by the quantity of them sold. It follows from this equation that there are only two *conceivable* ways in which the general consumer price level can rise. Namely, *either the demand for consumers' goods must rise or the supply of consumers' goods must fall*. If neither of these conditions is present, then it is absolutely impossible for the general consumer price level to rise. For there is simply no conceivable way that it could. Its rise in such circumstances would constitute a contradiction of the laws of arithmetic: it would be a rise in a quotient without a rise in the numerator or fall in the denominator, which is to say, an absolute impossibility.

This reduction of the possible causes of rising prices to just two does not actually rule out the existence of other possible causes, provided those other causes operate by way of producing more demand or less supply. More demand or less supply are the only conceivable proximate or direct causes of a higher price level. There is thus still the possibility of all kinds other, mediate or indirect causes of higher prices. However, the reduction to just these two proximate causes imposes a critical test on any other alleged cause. Namely, in the nature of the case, any cause of higher prices other than more demand or less supply must produce its effects by means of causing either more demand or less supply. If there is something which is alleged to be a cause of higher prices other than more demand or less supply, and it cannot be shown how it raises demand or reduces supply, then it must be dismissed as a cause out of hand. More demand or less supply are the necessary, indispensable connection between higher prices and any alleged other cause of higher prices. If they are absent, there simply is no connection between that alleged cause and higher prices.

The quantity theory of money connects the increase in the quantity of money to the rise in prices by way of establishing a connection to more demand. As previously explained, a growing quantity of money raises the demand for consumers' goods through the new and additional money being spent and respent and, as its rate of growth becomes more substantial, through bringing about a decrease in the demand for money for holding and thus a rise in the velocity of circulation of money.² Every other possible explanation of rising prices must pass a similar test of linkage to the growth in demand or decline in supply if it is to be considered.

The Elimination of Less Supply as the Cause of an Inflationary Rise in Prices

Our analytical framework for examining theories of the rise in prices is carried a long way forward when it is realized that *decreases in supply must be eliminated from*

consideration as the cause of a rising price level, both here in the United States and everywhere else in the world. There are seven reasons for eliminating reductions in supply. They are as follows.

i. The Actual Influence of Supply Has Been to Reduce Prices

In almost every year since World War II, which is the period complained of as marked by inflation, prices have indeed risen in the United States, Western Europe, and Japan. Yet, over the same period of time, supply has actually increased rather than decreased in these places, and it has done so in practically every year. Supply has increased enormously, as the result of a larger population, and, consequently, more people working; and, even more, as the result of technological progress and capital accumulation, which have raised the productivity of labor and thus enabled each worker on average to produce a greater output.

Our formula for the general consumer price level, of course, shows that the effect of increases in supply must be to reduce prices in inverse proportion. The fact that the price level has risen, therefore, despite vast increases in supply, can be ascribed only to the influence of even more substantial increases in demand. The problem of rising prices in the United States and every other leading country over the last fifty years or more is clearly one of rising demand, not falling supply.

ii. Where Falling Supply Has Contributed to Rising Prices, Its Role Has Been Relatively Minor

Of course, there are some countries in which supply has fallen, and fallen quite substantially, at least over portions of the period since World War II. Chile in the early 1970s and Uruguay in the 1960s are leading examples. While the precise extent of the fall in supply in these countries may be difficult to estimate, it is extremely doubtful that in the worst period the cumulative decrease ever exceeded a figure of 50 percent. If, for the sake of argument, we take the figure of 50 percent, we could account for a doubling of the price level in these countries on the basis of supply reductions. I say a doubling, because our formula for the general price level shows that a halving of supply coupled with an unchanged demand must produce a doubled price level. However, as is well-known, the price levels in countries like Chile and Uruguay have not increased by a factor merely of two over any extended number of years. An increase of this order of magnitude frequently occurs in a single year in those countries. In any given decade, prices in those countries have increased probably by a factor of fifty or more. And since World War II, they have increased by a factor of many thousand. Therefore, even where supply

has decreased, the overwhelmingly greater part of the rise in prices cannot be accounted for on the basis of reductions in supply, but must be ascribed to increases in demand.

iii. Reductions in Supply as the Cause of Rising Prices Imply the Rapid Disappearance of Material Civilization

Reductions in supply could explain a sustained significant rise in prices only if material civilization were in the process of rapidly disappearing, which, of course, it is not. For the price-level formula implies that every rise in the price level ascribable to a decrease in supply requires a decrease in supply that is inversely proportionate. This is because when changes in supply are supposed to be the operative factor, demand must necessarily be assumed to be unchanged. As a result, in the case of rising prices caused by falling supply, a rise in the price level means a rise in a quotient accompanied by a fixed numerator (demand). This implies a denominator (supply) that falls in inverse proportion. Thus, for example, a doubling of prices caused by a decrease in supply requires an actual halving of supply. In the same way, a tripling of prices ascribable to a fall in supply implies a reduction of supply to one-third of its initial level; a quadrupling, to one-fourth, and so on.

If a sustained rate of increase in the price level, such as 5 percent, 10 percent, or 100 percent per year, is to be ascribed to supply reductions, it follows that in each year, supply would have to fall in inverse proportion to the rise in prices. It further follows, therefore, that if any sustained, even moderately significant rate of increase in the price level were to be ascribable to supply reductions, the virtual disappearance of material civilization would be implied within a fairly short period of time. For example, in the course of a single generation, a 5 percent annual rise in prices based on supply reductions would mean that year after year, for a generation, supply would be on the order of 5 percent less than it was the year before. This would imply a cumulative reduction in supply to about one-third of its initial level, since at a 5 percent compound rate of increase, prices would approximately triple in a generation. If falling supply is to be the explanation of a tripling of prices, the fall would have to be all the way to one-third. With the same demand numerator, only such a fall in the supply denominator is capable of raising the price-level quotient by a factor of three.

Similarly, a 10 percent annual rise in prices, based on supply reductions and sustained for a generation, would imply a reduction in supply to about one-eighth of its initial level. This is because at a 10 percent compound annual rate of increase, prices double in approximately eight years. Thus, in a generation, which encompasses

more than three periods of eight years, in each of which prices double, prices must increase by more than two raised to the third power, that is, by a factor of more than eight. If falling supply is to be the explanation of an eightfold rise in prices, the fall would have to be all the way to one-eighth.

Even a mere 2 percent annual rise in prices caused by falling supply implies a halving of supply every thirty-five years and thus a reduction in supply to one-eighth of its initial level in the course of little more than a century. This is a more rapid rate of decline than was experienced by the Roman Empire in its decline. Thus it is not possible to explain a sustained rise in prices even as moderate as 2 percent a year on the basis of falling supply, without the very rapid disappearance of material civilization being present.

iv. Falling Supply Is the By-Product of Rapid Increases in Aggregate Demand

Furthermore, if we look at countries like Chile and Uruguay, which actually experienced significant supply reductions, it becomes obvious that most or even all of the reductions in supply that occurred were themselves the result of the rapid increases in aggregate demand that took place in those countries. A rapidly rising aggregate demand disrupts production. The rapid rise in prices it brings about causes widespread discontent and foments crippling strikes, and even sabotage. In these ways, and others that are more substantial, and which will be explained in Part B of this chapter, a rapidly rising aggregate demand acts to reduce production and, therefore, supply. Thus, a decrease in supply is often itself merely an indirect consequence of a rapidly rising aggregate demand, rather than being an initiating cause of rising prices.

v. Falling Supply Cannot Explain the Range of Price Increases that Exists Under Inflation

Even such supply reductions as are not themselves caused by rising demand, and which, therefore, may legitimately be said to be an independent cause of higher prices—for example, poor crops due to bad weather—should not be described as a cause of *inflation*, despite the fact that they raise the general consumer price level. This is because they do not produce the *range* of price increases that people associate with inflation. When people complain of “inflation,” they have in mind more than a mere rise in the weighted average of consumer prices that is depicted in the consumer price-level formula. They have in mind a condition in which almost every individual price rises and hardly any individual prices fall. It is highly doubtful that they would complain of inflation if a large number of individual prices actually

fell, even if, at the same time, the consumer price level, in the sense of the weighted average of consumer prices, rose. Yet precisely this phenomenon of widespread price declines would be the effect of reductions in supply that were not accompanied by increases in demand. If supply fell without being accompanied by an increase in demand, the effect would be that a whole host of prices would actually fall, even though the weighted average of prices rose.

A large number of prices would fall, because the effect of a reduction in supply would be to make people poorer. As they became poorer, they would concentrate a larger and larger proportion of their limited demand on necessities and a smaller and smaller proportion on luxuries. The prices of all luxury and semi-luxury items would therefore tend to fall.

To understand this result, consider the well-known fact that decreases in the supply of necessities produce more than proportionate increases in their price. A 5 percent reduction in the supply of wheat, for example, might raise its price by 25 percent, or more, because the price of a necessity must rise steeply before people are deterred from buying it. This kind of situation implies a shifting of spending away from comparative luxury goods, to wheat, or to any other necessity or comparative necessity in decreased supply. People have the money to pay the disproportionately higher prices of necessities in reduced supply only by taking money away from the purchase of luxuries. And that acts to reduce the price of luxuries. The principle here is that a drop in the supply of any good that comparatively speaking is a necessity causes spending to shift to it from goods that comparatively speaking are luxuries. Its price rises more than in proportion to the drop in supply, and their prices actually tend to *fall*.

Similarly, if the supply of any good falls that is employed with other, complementary goods, its price tends to rise disproportionately, while their prices actually tend to fall. For example, a drop in the supply of gasoline causes a sharp jump in the price of gasoline and, at the same time, acts to reduce the demand for automobiles, motel rooms, and so on. The prices of such things, therefore, tend to fall, and actually would fall if the quantity of money and demand in the aggregate did not rise and thus hold up or even increase the demand for them at the same time that people concentrated their expenditures more heavily on the goods in reduced supply.

The phenomenon of large numbers of prices actually falling as the result of declining supplies would be a continuing one as supply fell and the weighted average of prices rose from year to year. In one year, the prices of luxury goods and various complementary goods would

Figure 19-1
Falling Production and Supply Under an Invariable Money

fall as the prices of various necessities and certain complementary goods sharply increased. In the following year, as capital was withdrawn from the production of luxury goods and invested in the production of the necessities whose prices had sharply increased, the prices of those necessities would fall. Similarly, as capital was withdrawn from the production of complementary goods with depressed prices and invested in the production of complementary goods with sharply higher prices, the prices of the latter would come down. From year to year the rise in prices would outweigh the fall in prices, because of the overall reduction in supply. At the same time, however, numerous cases would always exist in which prices fell.

On the basis of this discussion, it should be clear that if not accompanied by an increasing aggregate demand, a reduction in supply would be accompanied by widespread declines in individual prices, even while the weighted average of prices rose. It would therefore not qualify as a cause of what most people have in mind when they complain of inflation. In order for practically every price to rise, there must be rising aggregate demand. That is the only way that the demand for some goods can increase without reducing the demand for other goods.

vi. Falling Supply Is Incompatible With the Debtor/Creditor Effects Associated With Inflation

Increases in the price level caused by supply reductions *do not produce the effects on the relations between debtors and creditors that people associate with inflation*. One of the major symptoms associated with inflation is that debtors gain at the expense of creditors. The debtors pay a contractually fixed rate of interest and are obliged to repay only a contractually fixed amount of principal. In a period of inflation, the debtors meet these contractual obligations in money of less value than they borrowed, and enjoy a gain at the expense of their creditors. For at the same time that prices rise, and reduce the purchasing power of the contractually fixed incomes and assets of creditors, the incomes and assets of debtors are free to rise without limit and generally do rise at a rate more rapid than prices. Thus debtors are enriched at the expense of creditors. The leading instance of this kind, of course, is that of stockholders—whose enterprises constitute a major category of debtor—being enriched at the expense of bondholders, a major category of creditor.

Now this phenomenon of debtors gaining at the expense of creditors, of stockholders gaining at the expense of bondholders, can occur *only if the rise in prices results from an increase in the quantity of money and volume of spending*—that is, from an increase in aggregate demand. It cannot occur if the rise in prices results from a

decrease in the supply of goods. It follows that if the debtor/creditor effects just described are to be regarded as an essential feature of inflation, inflation must be a phenomenon fundamentally of increases in money and spending, not decreases in production and supply.

Totally unlike the situation which prevails under inflation, the fact is that when prices rise because of falling production and supply, debtors do not gain at the expense of creditors. This can be clearly shown on the basis of Figure 19–1, titled “Falling Production and Supply Under an Invariable Money.” Figure 19–1 is the virtual mirror image of Figure 17–1, which dealt with the effects of rising production and supply under an invariable money.³ It provides the conditions for a virtual laboratory test of the effects of rising prices caused by falling production and supply on the relations between debtors and creditors, and will serve to demonstrate that in such conditions debtors do not gain at the expense of creditors.

In Figure 19–1, as in Figure 17–1, it is assumed that an existing IK of capital goods, when used in conjunction with IL of labor, makes it possible to produce either $2K$ of capital goods and $0C$ of consumers’ goods, at one extreme, or $0K$ of capital goods and $2C$ of consumers’ goods, at the other extreme, and that as the supply of capital goods changes, the overall ability to produce changes in direct proportion—e.g., doubling if the supply of capital goods should double, halving if the supply of capital goods should halve. Also, as in Figure 17–1, the simplifying assumption is made that all the capital goods in existence in any given year are productively consumed in that same year. Thus, as in Figure 17–1, it is necessary that the economic system devote half of its productive efforts to the production of capital goods if it is to maintain the existing supply of capital goods. The proportion of its productive efforts which it actually does devote to the production of capital goods is, of course, determined by the demand for capital goods relative to the demand for consumers’ goods.

As in Figure 17–1, the initial situation, depicted in *Year 1*, is that the demands for capital goods and consumers’ goods have been at the necessary $50/50$ ratio, with 500 monetary units being spent for each, every year. Finally, as in Figure 17–1, the demand for labor is assumed to be constant at 300 monetary units per year. It is on the basis of the application of these assumptions concerning the demands for capital goods and labor to *Year 0*, which is not described in the figure, that the cost values of the capital goods and consumers’ goods available at the start of *Year 1*, namely, 400 and 400, are derived. They are each 50 percent of 800, which is the sum of the 500 of demand for capital goods plus the 300 of demand for labor that took place in *Year 0*.

Figure 19–1, as I have said, is the virtual mirror image

of Figure 17–1. Thus, instead of net consumption falling from 200 to 100, as it did in Figure 17–1, it rises from 200 to 300, with the result that the demand for capital goods, instead of rising from 500 to 600, now falls from 500 to 400, while the demand for consumers' goods, instead of falling from 500 to 400, rises from 500 to 600. Thus, the relative demands for capital goods and consumers' goods change from $\frac{500}{500}$ to $\frac{400}{600}$ rather than to $\frac{600}{400}$, which last was the case in Figure 17–1.

The effect of this change in the relative demands for capital goods and consumers' goods is that starting with the production phase of *Year 1*, in which the changed relative demands of *Year 2* are anticipated and production adjusted accordingly, the economic system now devotes only 40 percent of its productive efforts to the production of capital goods, and 60 percent to the production of consumers' goods. The effect of this in turn is that the economic system becomes unable to produce a quantity of capital goods sufficient to offset the quantity of capital goods being used up in production. Thus while $1K$ of capital goods are productively consumed in *Year 1*, only $.8K$ of capital goods are produced for the start of *Year 2*, along with $1.2C$ of consumers' goods. In *Year 2*, which is the second year of the changed relative production of capital goods and consumers' goods, the overall ability to produce is reduced, because of the reduced supply of capital goods available at the start of the year. The ability to produce in *Year 2*, instead of being describable by the limits of $2K$ of capital goods and $0C$ of consumers' goods at one extreme, and $0K$ of capital goods and $2C$ of consumers' goods at the other extreme, is now 20 percent less, that is, describable by the narrower limits of $1.6K$ of capital goods and $0C$ of consumers' goods at one extreme, and $0K$ of capital goods and $1.6C$ of consumers' goods at the other extreme. This is because production takes place on the foundation of a supply of capital goods only 80 percent as large, namely, $.8K$ of capital goods instead of $1K$ of capital goods, and can therefore itself be only 80 percent as large.

The continuation of the $\frac{40}{60}$ ratio of the production of capital goods relative to the production of consumers' goods results in a supply of capital goods at the start of *Year 3* of $.64K$ (i.e., $.4 \times$ the limiting extreme of $1.6K$), and in a supply of consumers' goods of $.96C$ (i.e., $.6 \times$ the limiting extreme of $1.6C$). Thereafter, as the result of a process of less capital goods causing less productive ability, resulting in still less capital goods, and so on and on, in every year the supply both of capital goods and consumers' goods goes on falling—in the specific conditions of our simplified example, by exactly 20 percent per year.

Now although not explicitly shown in Figure 19–1, it follows inescapably, precisely because of the 20 percent

annual fall in supply in the face of a fixed aggregate demand, that the general price level both of consumers' goods and of capital goods rises at an annual rate of 25 percent from *Year 3* on. For example, in *Year 3*, 600 of demand for consumers' goods buys a supply of consumers' goods of only $.96C$, while in *Year 2* it bought $1.2C$ of consumers' goods. This represents a 20 percent reduction in the supply purchased for the same money. In *Year 4*, the same-sized aggregate demand for consumers' goods buys only $.768C$ of consumers' goods—that is, a supply reduced once more by 20 percent. Our knowledge of the price-level formula implies that where demand is fixed and supply is four-fifths as great, prices must be five-fourths as great, that is, 25 percent higher. And so it will be in every year beyond *Year 4*.

What is also the case in Figure 19–1 is that at no time is there an increase in the aggregate value of business assets. In *Years 1* and *2*, the opening assets of business are 1,800 monetary units. And in *Year 3* and every year thereafter, the opening assets of business are 1,700 monetary units, reflecting the rise in net consumption to 300 monetary units and fall in productive expenditure to 700 monetary units, which took place in *Year 2* and is maintained in every year thereafter.

Now the total value of business assets represents the sum of the equity and debt capitals invested in business, that is, the sum of the capitals invested by stockholders, partners, and proprietors, on the one side, and the sum of the capitals invested by bondholders and other creditors of business, on the other. The fact that nominal capital in the aggregate is fixed, or at least cannot increase (it did undergo a decrease), means that there is a loss as the result of rising prices caused by falling production and supply, not merely to bondholders and other creditors of business, *but to the owners of capital as such*. This means, it is not only bondholders and the like, whose assets are contractually fixed in money, who lose when production falls and prices rise, but the average capitalist as such—the average capitalist irrespective of whether he is a bondholder or a stockholder, that is, irrespective of whether he is a creditor-capitalist or a debtor-capitalist.

Indeed, if business had no debts whatever and there were only equity capital and thus every capitalist were in the position of being able to profit and add to his capital without any contractual limitations, the position of the *average* equity capitalist would be exactly the same as that of a bondholder. Some individual capitalists, to be sure, might gain. Not having their assets or incomes contractually fixed, they might earn extraordinary profits and accumulate nominal capital at a rate as fast or faster than the rate at which prices rose. But if the aggregate value of business assets and the average rate of profit is fixed, which are implications of a fixed quantity of

money together with a fixed rate of net consumption and a given array of marginal productivities of capital, then for every individual capitalist who earns a rate of profit above the average and who can add to his nominal capital, there are other individual capitalists who earn a rate of profit equivalently below the average and who equivalently consume their nominal capitals.

What stands out as clearly as possible in this case is that from the perspective of equity capitalists as a class, i.e., on the average, the effect of rising prices caused by falling production and supply is exactly the same as it is on creditor capitalists as a class. That is, on the average their capitals and incomes are fixed, and the rise in prices caused by the fall in production and supply reduces the purchasing power of their capitals and incomes, just as it reduces the purchasing power of the capitals and incomes of creditor capitalists.

It is not necessary to assume that business has no debts and that all capitalists are equity capitalists. This is because identically the same results follow if equity capital is any lesser proportion of the total capital invested in business firms. Thus, imagine that of the 1,700 monetary units of capital that is invested in business from *Year 3* on in Figure 19–1, half represents the equity capital of stockholders and the like, and half represents the debt capital of bondholders and the like. Both halves of the capital will lose to the same extent as the result of rising prices caused by falling production and supply. The same would be true if the proportions of equity and debt capital were one-fourth and three-fourths, one-tenth and nine-tenths, or any other proportions. By the same token, whatever portion of the 300 of aggregate profit generated by the 300 of net consumption in Figure 19–1 represents profit after deduction of interest and whatever portion represents interest, the purchasing power of both portions would be reduced equally by any rise in prices resulting from falling production and supply.

Thus, what Figure 19–1 shows is that if all that happens is a fall in production and supply, then it is certainly true that prices rise and creditors suffer, because their contractually fixed money revenues and incomes buy less, as do their assets, which are also contractually fixed in money. But in that case, debtors suffer equally from the rise in prices.

If prices rise because of falling production and supply, the money revenues and incomes of debtors do not rise on the average any more than those of creditors, which is to say, not at all. Nor does the money value of the assets of debtors rise on the average any more than that of creditors, which again is to say, not at all.

If the rise in prices is due to a fall in production and supply, while conditions on the side of money and demand are unchanged, then the aggregate money revenues

and incomes of the debtors are exactly what they were before the fall in supply and rise in prices. There is simply no possible basis of a rise in aggregate money revenues or incomes in the face of unchanged conditions of demand. This is because what unchanged conditions of demand mean is that the expenditures constituting sales revenues are the same and the productive expenditures giving rise to costs are the same. Thus aggregate sales revenues, aggregate costs, and aggregate profits are the same. In such circumstances, to whatever extent the average debtor sells at higher prices, he necessarily has *correspondingly less to sell*—precisely because the rise in prices is the result of less supply; indeed, as we know, in the conditions of a fixed aggregate demand, the rise in prices must be the result of an inversely proportionate reduction in supply. Thus, being able to earn no more money on average than he used to earn, the debtor's difficulty in repaying his debts can be no less than it used to be. This is illustrated in Figure 19–1 by the fact that in every year in which business debtors sell at 25 percent higher prices, they have precisely 20 percent fewer goods to sell. In other words, they are in the position of selling at five-fourths the prices only four-fifths the quantity of goods, which means they take in only the same amount of money revenue. And with the stabilization of aggregate productive expenditure and thus costs, their money net incomes also become fixed. Indeed, having to repay the same debt out of the same revenue or income in the face of higher prices for what one buys, makes the repayment of debt more difficult than it was before, because of the reduction in one's real disposable revenue or income.⁴

Similarly, to whatever extent the price of the average debtor's capital assets rises, because of a reduction in their supply, there is nothing present to increase the aggregate value of such assets or, therefore, the value of the capital assets in the possession of the average debtor. In the absence of an increase in the quantity of money and volume of spending, the rise in the average price of capital assets is merely in inverse proportion to the decline in their supply. Indeed, insofar as decreases in supply are the result of a lower economic degree of capitalism or lower degree of capital intensiveness in the economic system, the aggregate monetary value of the assets of debtors (and creditors) is less in the face of any given quantity of money and volume of spending of the kind that generates business sales revenues, because it reflects less saving and productive expenditure relative to any given amount of sales revenues. Precisely this, of course, is the situation in Figure 19–1, in which the aggregate capital invested in the economic system falls from 1,800 monetary units to 1,700 monetary units between *Years 1* and *3*.

Going still further, in the case of rising prices caused by falling supply, it is easy to imagine conditions in which individuals would be *worse off* as debtors than as creditors. Thus, for example, imagine a war, with massive bombing and shelling, which destroyed a major portion of the plant and equipment of every firm, but which was not accompanied by any change in the quantity of money or volume of spending in the economic system. In this case, production would be greatly reduced, and prices would correspondingly rise. Creditors would lose a corresponding portion of their buying power, because their money incomes and assets would be fixed. But debtors would lose even more of their buying power. This would be the case because not only would they too have to pay the higher prices, but also the money value of their assets would actually be sharply reduced, in that, as equity owners, they would suffer the full loss in the value of the assets of their firms before the creditors suffered any loss. The debtors—not only business debtors such as stockholders, but also owners of homes that were damaged and on which there were mortgages—would suffer the loss of a major portion of their monetary net worth at the same time that they faced the need to pay higher prices.⁵

In the case of rising prices caused by falling supply, it is likely that debtors would actually experience conditions closer to those of *deflation* than inflation. By this, I mean that to some extent their revenues and incomes would actually fall for a time, precisely as the result of the fall in production and supply. To understand this phenomenon, recall that back in Chapter 13 I showed that

in the case of goods with major accumulated stocks, such as housing and automobiles, in which the funds expended in the purchase of previously produced goods can far exceed the funds expended in the purchase of newly produced goods, the effect of increases in production would be to increase the size of the market for newly produced goods relative to the market for previously produced goods and thus to draw funds to the former from the latter.⁶ In the present, opposite case of falling production, the size of the market for newly produced goods declines relative to the market for previously produced goods, whose accumulated stocks reflect the greater production of prior years. As a result, funds are now drawn to the market for previously produced goods and away from the market for newly produced goods. In this way, the demand for the goods and services of business firms, which, of course, are engaged overwhelmingly in new production, is correspondingly reduced.

Along the same lines, as a further irony, insofar as the effect of a reduction in production is a reduction in the production of commodity money, the result, as a minimum, is a reduction in the rate of increase in the quantity of money and volume of spending. Thus, the effect is a greater difficulty, compared to what it otherwise would have been, of earning any given sum of money and thereby repaying debt. Thus, in this way too, the effect of reductions in production and supply is directly contrary to the debtor/creditor effects associated with inflation, irrespective of any rise in prices that may result.

All of the foregoing leads to the conclusion that in

Figure 19–2

The Initial Balance Sheet of a Hypothetical Average Firm Before a Rise in Prices Resulting from Any Cause

ASSETS	LIABILITIES
<hr/> <p>\$2,000,000 representing a given quantity of plant, equipment, and inventories at a given level of prices and capable of producing a given physical volume of output at a corresponding level of prices.</p>	<hr/> <p>\$1,000,000 of debt to bondholders and other creditors.</p> <p>\$1,000,000 net worth of stockholders.</p> <hr/> <p>\$2,000,000</p>

order to account for the phenomenon of debtors gaining at the expense of creditors, the rise in prices must originate *on the side of money and demand, not supply*. There must be more aggregate demand, due to the increase in the quantity of money. This alone is what raises the sales revenues, money incomes, and property values of debtors as a class and thus makes debt repayment easier for them. In this case, the increase in their money incomes and money net worths can outstrip the rise in prices to the same extent as the fixed money incomes and asset values of the creditors fall behind the rise in prices.

The complete dependence of the debtor/creditor effects associated with inflation on the increase in the quantity of money and volume of spending in the economic system, can be illustrated in terms of a series of balance sheets for a hypothetical average business firm. These are shown in Figures 19–2, 19–3, and 19–4.

Figure 19–2 describes an initial state of affairs, in which the average business firm has total assets worth \$2 million, \$1 million of which represents capital supplied by bondholders—creditors—and \$1 million of which represents capital supplied by stockholders—debtors. At the same time, the \$2 million of assets reflect a given physical supply of capital goods, in the form of plant, equipment, and inventory, at a given average unit cost of capital goods.⁷ This supply of capital goods is capable of producing a given volume of physical output. When the combined consumers’ goods output of all such firms in the economic system is divided into a given aggregate demand for consumers’ goods, the result is the initial

general consumer price level.

Figure 19–3 shows an average balance sheet for conditions in which prices have doubled owing to a halving of supply. Here, because conditions on the side of money and demand remain the same, \$2 million is still the monetary value of the assets of the average business firm, with the only difference being that now \$2 million represents half the physical quantity of capital goods at twice the average unit cost of capital goods. In this case, the bondholders continue to have their million of capital and the stockholders continue to have their million of capital. Both classes of investors lose equally in terms of the buying power of their assets, which is cut in half because of the doubling of the price of consumers’ goods that results from the halving of the supply of capital goods and thus of the ability to produce consumers’ goods.⁸

Only in the conditions of Figure 19–4, where the doubling of prices results from a doubling of the quantity of money and volume of spending, are the stockholder/debtors as a class in a position to gain as prices rise. Their gain results from the fact that the increase in the quantity of money and volume of spending increases the money revenue and income of the average firm at the same time that it raises prices. Because of the rise in its revenue and income, the average firm is enabled to increase its saving and reinvestment. The result is a rise in the total monetary value of the capital assets of the average firm. This increase, of course, accrues to the benefit of the stockholder/debtors, not to the benefit of the bondholder/creditors, whose incomes and assets are contractually fixed.

Figure 19–3
The Balance Sheet of a Hypothetical Average Firm Following a Rise in Prices Caused by a Halving of Supply

ASSETS	LIABILITIES
<hr style="width: 80%; margin: 0 auto;"/> <p style="margin-top: 10px;">\$2,000,000 representing half of the initial quantity of plant, equipment, and inventories at double the initial level of prices and capable of producing half the physical volume of output at a doubled level of prices.</p>	<hr style="width: 80%; margin: 0 auto;"/> <p style="margin-top: 10px;">\$1,000,000 of debt to bondholders and other creditors.</p> <p style="margin-top: 20px;">\$1,000,000 net worth of stockholders.</p> <hr style="width: 80%; margin: 0 auto;"/> <p style="margin-top: 10px;">\$2,000,000</p>

Thus, in Figure 19–4, the money value of the assets of the average firm has doubled from \$2 million to \$4 million. The capital of the bondholder/creditors is contractually fixed and therefore remains at \$1 million. Accordingly, the \$2 million increase in the value of the assets of the average firm accrues to the stockholder/debtors, whose capital thus rises from \$1 million to \$3 million. In these circumstances, as prices double, the bondholder/creditors, whose assets remain fixed, suffer a 50 percent loss in real wealth. The stockholder/debtors, on the other hand, whose nominal capital triples when prices double, obtain a 50 percent gain in real wealth. Exactly the same results apply to real income, inasmuch as the doubling of money and spending results in a doubling of profits gross of interest. With the amount of interest contractually fixed, the increase in gross profits accrues to the benefit of the stockholder/debtors. A doubling of prices thus represents a halving of the real incomes of the bondholder/creditors and an equivalent increase in the real incomes of the stockholder/debtors.

Of course, the stockholder/debtors will not be able permanently to gain in this way. The rise in the nominal rate of profit that is caused by the increase in the quantity of money and volume of spending sooner or later raises the nominal rate of interest correspondingly. From that point on, continued inflationary gains of the stockholder/debtors at the expense of the bondholder/creditors depend on a further acceleration of the inflation.

Before leaving the subject of debtor/creditor effects,

it is important to bear in mind that in the absence of an increase in the quantity of money, any rise in the rate of profit inaugurated by a rise in the rate of net consumption, such as occurs in *Years 2 and 3* of Figure 19–1, is accompanied by a reduction in the aggregate value of capital assets.⁹ This is because the corollary of a higher rate of net consumption in such circumstances is an absolute decline in saving and productive expenditure, which serves to reduce the aggregate, accumulated value of capital assets. Thus, even if it were the case that alongside of rising prices resulting from falling production and supply, the rate of profit were temporarily to rise relative to contractually fixed interest rates that were geared to a preceding, lower rate of profit, and thereby give business borrowers a temporary advantage at the expense of their creditors, it would still not be proper to describe the situation as one of inflation. In such circumstances, precisely during the time in which the rate of profit was rising, both sets of capitalists would experience an actual decline in their nominal capitals. This, of course, is the exact opposite of what goes on under inflation, where the increase in the quantity of money and rise in the rate of profit and interest results not only in stockholder/debtors but also in bondholder/creditors adding to their nominal capitals.¹⁰

Moreover, the very fact that the process is the result of a rise in the rate of net consumption and corresponding fall in saving operates to raise the rate of interest immediately. The rate of interest rises as the result of a reduction in the supply of savings, and thus of available

Figure 19–4
The Balance Sheet of a Hypothetical Average Firm Following a Rise in Prices Caused by a Doubling of Money and Demand

ASSETS	LIABILITIES
<p>\$4,000,000 representing the initial quantity of plant, equipment, and inventories at double the initial level of prices and capable of producing the initial physical volume of output at a doubled level of prices.</p>	<p>\$1,000,000 of debt to bondholders and other creditors.</p> <p>\$3,000,000 net worth of stockholders.</p> <hr style="width: 100%;"/> <p>\$4,000,000</p>

credit, in the face of the prevailing initial rate of profit. Indeed, it is probable that the rise in the rate of interest would actually precede the rise in the rate of profit, which would be delayed insofar as negative net investment took place. (Extensive negative net investment is not shown in Figure 19–1, because of the simplifying assumption that all capital goods in existence at the beginning of any year are used up in that same year. It would exist in reality, however.) Thus, in the case of a rise in the rate of profit caused by a rise in the rate of net consumption, there would be no sudden surge in the rate of profit in the face of a large volume of contractually fixed interest rates geared to a substantially lower rate of profit, which, of course, is what occurs in a period of inflation. This conclusion is reinforced by the fact that the rise in the rate of net consumption would itself almost certainly be slow and gradual rather than sudden and precipitous. Indeed, the very fact that in the absence of an increase in the quantity of money and volume of spending in the economic system, a rise in the rate of net consumption entails a fall in saving and productive expenditure, resulting in negative net investment and capital decumulation, and correspondingly reduces the availability of credit, gives the situation much of the character of a period of deflation and financial contraction, despite the existence of rising prices.¹¹

On the basis of all of the preceding, it should be clear that the debtor/creditor effects associated with inflation can take place only on the foundation of an increase in the quantity of money and volume of spending. A rise in prices resulting from a decrease in production and supply would simply not be accompanied by such effects. Thus, if debtors gaining at the expense of creditors is to be regarded as an essential symptom of inflation, it follows that inflation is a matter of increases in money and spending, not decreases in production and supply.

vii. Falling Supply as a Cause of Inflation Implies That Rising Supply Is a Cause of Deflation and Depression

Finally, there is still one more reason for excluding higher prices caused by less supply from the category of inflation. And that is that if they are described as inflation, it implies the absurdity that more supply—more wealth—is the cause of depressions and poverty. Because if higher prices due to less supply are inflation, then it follows that lower prices due to more supply are deflation. But deflation is virtually synonymous with a depression, which is a state of poverty. Thus, if we say that higher prices due to less supply are inflation, we imply that more supply causes deflation, depression, poverty. This is a self-contradiction, no less absurd than such 1984 notions as “war is peace” and “freedom is

slavery,” because more supply means more goods, which, of course, means greater prosperity.¹² Thus, in addition to all of the other reasons I have given, we should avoid describing rising prices caused by falling supply as inflation, in order to avoid being guilty of this contradiction.

The truth is that both inflation and deflation are concepts that do not pertain to changes in the price level per se, but, at most, only to changes in the price level that originate *on the side of money and demand*.¹³

We have now eliminated reductions in supply as a cause of “inflation.” We have eliminated them, first of all, as a significant factor in raising prices (points i–iii) and have shown that to an important extent reductions in supply are themselves the result of rapid increases in aggregate demand (point iv). And, to the extent we have not totally eliminated reductions in supply as a factor in raising prices, we have shown that such price increases as they do cause cannot properly be described as inflation. They cannot, because they contradict important symptoms of inflation (points v and vi), and because to describe them as inflation implies the absurdity that wealth is the cause of poverty (point vii).

This means that we have narrowed the problem of inflation down exclusively to one of rising aggregate demand, which our formula for the general consumer price level shows to be the only conceivable remaining explanation. Thus, we are now in a position to show why all of the explanations of an inflationary rise in prices other than the quantity theory of money are either totally false or must be interpreted as giving further confirmation of the quantity theory of money.

2. Refutation of the “Cost-Push” Doctrine in General

The supporters of the cost-push doctrines recognize the validity of the formula for the general consumer price level. However, they perceive the role of rising demand in a different way than do the supporters of the quantity theory of money. While the supporters of the quantity theory of money see more demand as the cause of higher prices, the supporters of the cost-push doctrines see it as the cause of greater production and supply. In their view, more demand causes correspondingly more production and supply and therefore does not raise prices. The reason the supporters of the cost-push doctrines believe this is because they see the existence of unemployed labor and idle plant capacity, and they assume that so long as unemployment and idle capacity exist, the effect of more demand is simply to enable more people to be employed and therefore for production to be increased.

The supporters of the cost-push doctrines are willing to concede that more demand is potentially capable of

raising prices. But that, they say, could happen *only* in the context of an economy operating at full employment and in which, therefore, supply could not be further increased in response to more demand. At that point, they are willing to admit, more demand would not be accompanied by more supply and would thus drive up prices. The expression they use to describe this situation of more demand raising prices at the point of full employment is, of course, “demand-pull inflation.” At the point of full employment, they say, more demand “pulls up” prices. This so-called demand-pull inflation is the only potential influence of more demand on prices that they recognize. To them, more demand as a cause of inflation means “demand-pull inflation.”¹⁴

Observe how the supporters of the cost-push doctrines think. They have decided that more demand is capable of raising prices only at the point of full employment. They have decided that short of full employment, the effect of more demand is not higher prices, but more supply. These are the assumptions they bring with them when they observe that since World War II our economic system has not operated at full employment. As a result, they then conclude that they are free to dismiss rising demand as the cause of rising prices in the United States, because—as explained—they have already relegated more demand as a possible cause of rising prices to the arbitrarily limited context of full employment.

It is on this basis that they turn to the various forms of the cost-push doctrine as an explanation of the rising prices experienced since World War II. In their eyes, more demand cannot explain these price increases, because they occurred in the absence of full employment. Thus, some other explanation must be found. The reason rising costs are taken as the explanation is because, in fact, the prices of many goods are determined in the first instance on the basis of their cost of production, as I showed in Chapter 6 of this book.¹⁵

Of course, I also showed that all prices determined by cost of production are *ultimately determined by supply and demand*, so there is no contradiction involved in my conceding the role of cost of production in determining prices and, simultaneously, arguing that all prices are determined by supply and demand. Cost of production—and this point is relevant now—is always based on prices, including wages, which are the price of labor. For example, the cost of producing a bicycle is based on the wages of the bicycle workers, the price of the steel that goes into the bicycle, and so on. It follows that cost of production can never be an ultimate explanation of prices, but just an intermediary explanation of some prices on the basis of other prices—for example, an explanation of the price of the bicycle on the basis of the prices of the labor and steel and so forth that are used to produce it.¹⁶

The fact that cost of production is not an ultimate explanation of prices constitutes a major logical deficiency of the cost-push doctrine. Because what the cost-push doctrine is actually claiming is that some prices rise because other prices rise, and it is content to leave matters at that. For example, the supporters of the cost-push doctrine blame inflation on such things as the rise in the price of steel or the rise in wages achieved by various unions. They do not offer any explanation of what makes possible the higher price of steel or the higher wages obtained by the unions.

In fact, as already shown, what the cost-push doctrine boils down to is the claim that certain key prices, and this includes wages, rise arbitrarily, without any explanation other than the greed of those who raise them. The cost-push doctrine, in the last analysis, is a doctrine that tries to blame price increases on some form of arbitrary power. It tells us, in effect, that prices rise simply because some powerful people are making them rise.

Now it is true that in our present economic system, that is heavily overlaid with government regulations and controls—i.e., the so-called mixed economy—arbitrary power does exist. There are labor-union monopolies in a position to force employers to agree to almost any wages they ask. There are also some business monopolies, such as government-franchised electric utilities (though the business monopolies are generally regulated in the prices they can charge).

Nevertheless, even the existence of arbitrary power on the part of sellers cannot explain rising prices. I will explain this more fully in the specific discussions of the wage-push and profit-push doctrines that follow. But this much can be said right now: The basic reason why arbitrary power on the part of sellers is not a sufficient explanation of rising prices is that such higher prices as it might bring about *always cause reductions in the quantity of the good or service that can be sold and, therefore, act as a brake on any further such price increases*. This is closely related to an even more fundamental objection, namely, that *the cost-push doctrines are equivalent to an attempt to blame inflation on falling supply*, which we have already seen is invalid.

In order to prove this equivalence, all that is necessary is to perform a kind of mental experiment in terms of the price-level formula

$$P = \frac{DC}{SC}.$$

Our mental experiment consists simply of this: We assume that monopolistic sellers arbitrarily drive up prices, just as the cost-push doctrine claims. But we also assume that while this rise in prices occurs, there is no change in aggregate demand. We make this second assumption

because if the rise in aggregate demand is really not a factor in raising prices, as the supporters of the cost-push doctrine tell us, then its absence can make no difference.

Thus, what we have is a rise in prices and a fixed aggregate demand—a fixed amount of spending. In terms of the elements of our formula P is up, while D_C is fixed.

Nothing could be more obvious than the result of this experiment. Namely, S_C must fall in inverse proportion to the rise in P . The higher the monopolistic sellers would drive the price level, the less would be the supply of goods they could sell—in inverse proportion.

Let us appraise the results of this experiment. We see the quantity of goods sold falling to the same extent that the monopolistic sellers force up prices. There is no essential difference between this case and the cases discussed previously in which a fall in supply raised prices—they are mathematically equivalent. A fall in supply is a mathematically indispensable condition for the rise in prices, whenever demand remains fixed. Thus, it is absolutely essential for the monopolistic sellers to reduce the supply of goods or services that are sold, if they are to drive up prices. If they did not do this, they simply could not raise prices. It is precisely because the monopolistic sellers must hold down supply to raise prices, that they want to prohibit other people from selling and to be monopolists in the first place. For example, the reason a monopoly labor union wants to control apprenticeship programs and make it as difficult as possible for people to enter an occupation is that that is a way of restricting supply and thereby making it possible for the union to drive up wages. In the face of a fixed demand, the mere fact of establishing higher wages or prices for the labor or goods that are sold serves to reduce the supply that is sold in inverse proportion. The unions and the other monopolists want to restrict as far as possible the supply that is or potentially could be offered by competitors, in order to minimize the reduction in the quantity that they themselves can sell.

The fact that the various cost-push doctrines are the same as an attempt to blame inflation on falling supply totally invalidates them. Because it means that all of the objections raised previously against falling supply as a cause of rising prices apply with equal force against cost-push as a cause of rising prices.

It is now possible to deal with each of the specific versions of the cost-push doctrine, in the light of the knowledge of what the doctrine in general implies about supply.

3. Critique of the “Wage-Push” Variant

The wage-push argument is the most plausible version of the cost-push doctrine, because what it really refers to are the activities of legally privileged, government-pro-

tected labor unions. Such labor unions possess monopoly powers in that employers are compelled by law to deal with them and either to meet their wage demands or do without labor; in addition, these unions are often in a position to resort to direct intimidation and violence to back up their demands, without fear of legal reprisal. Because of these monopoly powers, the unions are able to set wages as high as they like. Even nonunion employers must adopt the pay scales set by the unions, lest their workers decide to unionize, which they can easily do. In this way, the unions are able to drive up wage rates, costs of production, and thus prices, throughout the entire economic system.

Nevertheless, as destructive as this power of the present-day unions is and as serious as its consequences are, if this were the only factor at work—if it were not joined by an expanding quantity of money and a rising aggregate demand—it would not be possible for the unions to exert any long-run or significant influence in making prices rise. In fact, on a long-run basis, prices would probably fall in an economy such as ours, despite the activities of the unions. The fact is that it is only an expanding quantity of money and a rising aggregate demand that permit so-called “wage push,” or any other form of “cost push,” to go on “pushing” very far.

The reasons are as follows. If demand—spending—did not rise, if it stayed the same, any increase in the general price level brought about by “wage push” would be accompanied by a corresponding decline in the supply of goods that could be sold, as we just saw in our mental experiment concerning the effects of cost push. This decline in the quantity of goods that could be sold at higher prices would cause a corresponding reduction in the quantity of labor that employers could profitably employ. Because if the quantity of goods employers can sell falls, they obviously require less labor for production. The same conclusion follows even more directly from the effects of higher wage rates in the face of a limited aggregate demand for labor, i.e., limited total payrolls in the economy. Because the total funds available for meeting payrolls are limited, employers simply do not have the financial means of employing as many workers at higher wage rates as they do at lower wage rates.

Now this mounting reduction in the volume of employment offered every time wages and prices were increased would place a limit on the extent to which the unions would drive up wages and prices. *So-called wage-push inflation would burn itself out in mounting unemployment.* Every time a union sought a wage increase, it would have to count the number of its members it was prepared to see added to the ranks of the unemployed. The point would soon be reached where the sheer volume

of their own unemployed members would stop further wage demands even on the part of the worst monopoly labor unions.

In order to appreciate just how limited would be the power of monopoly unions to raise prices without the aid of a rising aggregate demand, let us perform another mental experiment. Let us imagine that we have full employment and that aggregate demand is fixed. Now let us trace the consequences of the unions driving up the wage and price level by varying amounts. Each time they raise wages and prices, the quantity of goods that can be sold falls, the quantity of labor required in production falls, and the unemployment rate grows. The question we want to ask is: If the unions were willing to drive the unemployment rate to the height that prevailed in the worst years of the 1929 Depression before stopping in their wage demands, how much could they raise prices?

The unemployment rate in 1932 and 1933 was about 25 percent of the labor force. If it took that kind of staggering unemployment rate to stop the further demands of the unions, it would be implied that the maximum cumulative limit by which the unions could raise wages and prices would be one-third, and no more. That degree of wage and price increase would produce a 25 percent unemployment rate.

These conclusions follow mathematically, on the basis of the price-level formula. A 25 percent unemployment rate leaves a 75 percent, positive employment rate, i.e., the number of workers employed is reduced to three-fourths of the initial number. In these conditions, production and supply can be presumed also to fall to three-fourths of their initial level. (If the operation of the law of diminishing returns is allowed for, production and supply would not fall this much: the loss of the last one-fourth of the labor employed would reduce production by less than one-fourth.) The price-level formula, of course, shows that if supply is three-fourths, while demand is fixed, prices must be four-thirds:

$$\frac{4}{3}P = \frac{DC}{\frac{3}{4}SC}$$

Prices of four-thirds mean a rise in prices of one-third. Hence, the movement from a zero unemployment rate to a 25 percent unemployment rate would be accompanied by a rise in the price level on the order of one-third. Or, conversely, starting from full employment, driving up wages and prices by one-third would produce an unemployment rate of 25 percent.

This rise in prices and unemployment might take place all at once, or it might occur gradually over many years, depending on how rapidly or slowly the unions forced up wage rates. But whether it occurred rapidly or

slowly, one-third or some amount not much greater than a third, and probably quite a bit less, would be the maximum cumulative limit of a rise in prices ascribable to monopoly labor unions. Because the fact is that the ability of the monopoly unions to raise wages and prices is severely limited by the effect of such wage and price increases on the unemployment rate, and it can be safely assumed that even the monopoly unions would be deterred from further wage demands in the face of an unemployment rate at the level of a catastrophic depression. Indeed, the experience of the early 1980s showed that the unions were willing sharply to reduce their wage demands in the face of an unemployment of 10 or 11 percent and even to accept wage reductions in a number of cases.

Moreover, once the unions decided to stop their demands, and the unemployment rate stabilized, at however high a level, prices would probably actually *fall*.

The fall in prices would occur as the result of technological progress and capital accumulation, or any other factor that increased the productivity of labor—that is, which enabled a unit of labor, on average, to produce more. Increases in the productivity of labor, of course, mean that larger supplies of goods are produced by the same number of workers and that each unit of goods has a lower cost of production, because it takes less labor to produce it. A rise in the productivity of labor acts to reduce prices, because it means both larger supplies and lower unit costs. It is an offset to “wage-push.”

To illustrate this point, let us assume that after the unions had raised the wage and price level by the limit of a third, the productivity of labor began to increase, as the result of the application to production of a series of inventions. Assume that over a period of years the cumulative effect of these inventions was to double the productivity of labor. In that case, the three-fourths of the labor force that was employed would produce twice as much as it previously did. Prices, therefore, would fall by half in comparison with the point to which the unions had raised them. And that would mean that they would actually be lower than they were before the unions began their activities. They would be half of four-thirds, i.e., only two-thirds of their initial height. In terms of our formula,

$$\frac{1}{2} \times \frac{4}{3}P = \frac{DC}{2 \times \frac{3}{4}SC}$$

To the extent that increases in the productivity of labor occurred at the *same time* that the unions were driving up wage rates and creating unemployment, their effect would be to offset the rise in costs and decline in production attributable to the unions. It might very well be the

case, therefore, that the unions alone would not be able to raise the price level even temporarily.

On the basis of these considerations, we must conclude that it would simply be impossible for monopoly labor unions, unaided by increases in the quantity of money and rising aggregate demand, to make any sustained significant contribution toward raising the general price level. Indeed, in the absence of an expanding money supply and rising aggregate demand, the long-run effect of the unions on the price level, and probably the short-run effect too, would most likely be not to raise it in any absolute sense, but merely to reduce the rate at which it had fallen.

Unaided monopoly unionism, or “wage push,” is not the cause of rising prices but of *mass unemployment*. As I have shown, the rise in prices it might bring about would be essentially nonrepeatable, would probably be temporary at most, could never be of really major significance as price increases go, and could easily be far more than offset by increases in the productivity of labor, with the result that prices actually fell, though by less than they otherwise would have. But the unemployment monopoly unionism creates remains, and is of major significance.

The problem of unemployment leads us to the real connection between monopoly unionism and rising prices. Because what the government does when confronted with the prospect of rising unemployment is to *inject a larger quantity of money into the economic system*. The additional demand that results permits the unions to drive up wages and prices without causing corresponding additional unemployment.

The fact that the quantity of money and demand are made to increase more or less in pace with the wage demands of the unions is the only thing which permits the phenomenon of “wage push” to continue in existence, because it removes the brake that would otherwise be supplied by a mounting rate of unemployment. In other words, it is the government’s expansion of the money supply that is the only thing that allows the unions to go on “pushing” wage rates and prices up very far. To put it in still a different way, no more “wage-push inflation” exists than the government is willing to provide an expanding quantity of money to finance.

The government and the economists who support it chronically evade the very necessary, critical role of the expansion of the money supply. As they describe matters, the unions simply drive up wages and prices without limit, and the government has nothing whatever to do with the matter. Its role is merely to urge the unions to exercise “restraint.”

The fact is that the government’s expansion of the money supply and thus of aggregate demand positively

encourages the wage demands of the unions, and does so even in the midst of mass unemployment. As we have seen, it calls union wage demands into being when they would otherwise not have existed—by removing the brake on wage demands constituted by the prospect of adding further to the already existing level of unemployment; by enlarging nominal profits, which constitutes a veritable red flag to the unions and their demands for wage increases; and by causing prices of goods available only in limited quantity to rise, which, together with rising prices caused by the unions’ previous wage demands, leads the unions to demand wage increases to keep pace with price increases.¹⁷ And then, of course, the government’s expansion of the money supply and aggregate demand enables the unions to go on endlessly repeating the imposition of their demands, by removing the consequence of mounting unemployment.

Thus, the government’s expansion of the money supply must be regarded as the cause of the far greater part of “wage push”—as the cause of *all* of wage push insofar as the phenomenon is continuing and can be associated with a problem of inflation. To whatever extent there is an element of truth in the existence of “wage push,” the phenomenon must be regarded as an extension of the influence of the quantity of money, whose increase operates not merely through “demand pull,” but no less by means of making possible and, indeed, positively instigating wage push. In effect, the intellectual zone of explanation of rising prices previously regarded as belonging to the wage-push doctrine should henceforth be regarded as having been annexed by the quantity theory of money.

4. Critique of the “Profit-Push” Variant

According to the “profit-push” doctrine, prices rise primarily not because wages are rising but in order to increase the profits of “powerful monopolists” and “greedy big businessmen.” It is the push for ever higher profits, say the supporters of this doctrine, that initiates the so-called wage-price spiral, because the unions, it is alleged, demand wage increases only to keep pace with price increases and the cost of living.

Needless to say, the profit-push doctrine is enormously popular with the monopoly labor unions and their numerous supporters. All things considered, it is probably by far the most popular explanation of inflation, because, as we have seen, it is directly implied by the definition of inflation as rising prices.

Now, in fact, the profit-push doctrine is subject to all the essential criticisms made of the wage-push doctrine, plus some others. It ignores the fact that in the absence of rising demand, rising prices reduce sales volume—

that is, they reduce the quantity of goods that can be sold. The prospective loss of sales volume makes even a government-protected monopolist limit his price at some point.

Indeed, let us consider precisely the case of a government-protected monopolist, because that case provides the most plausible context for the profit-push doctrine. Yet it is very easy to show that the doctrine cannot apply even there. And if it cannot apply there, it obviously cannot apply to any case in which the freedom of competition exists.

Thus, let us imagine a government-franchised electric utility that has been given the exclusive legal privilege of selling electricity in a given geographical area. Such a utility is protected from competition by law. Let us imagine further that the rates charged by this utility are not subject to any form of government regulation—it can legally charge any rate it likes. Nevertheless, even such a utility would still be limited in what it could charge by the forces of the market. It would not want to charge rates so high as to discourage large numbers of business firms from locating or remaining in its area. It would not want to charge rates so high as to discourage large numbers of home-owners from using electric heat or buying electrical appliances. Clearly, there would be a limit to what such a utility would charge, given the conditions of demand confronting it.

Now the prices charged by this uncontrolled monopoly utility might be considerably higher than the prices that would be charged under the freedom of competition or under government rate control. But what it is crucial to realize is that there is absolutely no reason why the utility would want to go on *raising* its price year after year. Such a monopoly could find it profitable to charge a very *high* price perhaps, but not a steadily *rising* price. Its interest would lie in picking the price that maximized its profits, and then *sticking to that price*. Given the same conditions of demand confronting it in the present as in the past, the monopoly would not raise its price in any given year for the same reason that it did not already charge that price in the year before—namely, it would lose too much business by doing so.

In order for the monopoly to find it to its interest to raise its price every year, the conditions of demand confronting it must be changing. People must have a growing ability to pay for its products. But how do people obtain that ability? One way might be if the prices of other things they bought were falling. This would release funds they previously required for other purposes. But observe. In this case, the rise in utility rates presupposes a fall in other prices and is strictly limited by the extent of their fall. This case, therefore, cannot be a case of a rise in the *general* price level. In this case, therefore, the

problem of inflation does not even come up, but just a rise in some prices accompanied by a fall in other prices.

Another way people might be able to afford to spend more for electricity would be if they simply increased their relative valuation of electricity in comparison with goods they were previously buying. They might just decide, in other words, that they wanted to spend more for electricity and less for other things. But consider. This case means that the rise in demand for electricity is accompanied by an equivalent drop in the demand for other things. The effect of the drop in demand for other things is either to reduce the prices of other things or the supply of other things that is sold. In either event, the problem of inflation again does not come up—because we either have no rise in the general price level or one that can only be associated with a decrease in supply.

In order for the utility's rate increase to be connected with a problem of *inflation*, its customers must be in a position to enlarge their spending for electricity *without* having to reduce their spending for other things. But this means they must be in a position to make a larger *aggregate demand*. Consequently, the only possible explanation of how even protected legal monopolists could raise their prices in a way that is relevant to the problem of inflation is that of a growing aggregate demand. And this, of course, in turn depends on an increasing quantity of money.

It must be stressed that with the exception of the cases in which the government violates the freedom of competition, it is a total reversal of things to regard the quest for higher profits as a cause of higher prices. As we have seen, where the legal freedom of competition exists—that is, where the government does not stand in the way of men competing—the quest for higher profits is always the cause of more supply and *lower* prices. This is because, as I demonstrated in Chapter 6, under the freedom of competition firms can earn higher profits only by introducing new and improved products, by finding ways to cut the costs of production, and by keeping the relative production of the various goods properly adjusted to the changing needs and wants of the consumers. As I showed, all of this represents an expansion in production and, therefore, a tendency toward a lower price level. It was nothing but the quest for higher profits that developed all of our industries and built our entire economic system over the last two hundred years. The effect of this has certainly been to make prices vastly lower than they would otherwise have been, because it has radically increased supply. Thus, the profit motive is, in fact, the source of lower prices, not higher prices. This conclusion is further strengthened if we look at what is done with most large profits after they are earned. Most such profits

are saved and invested. This, in turn, means more factories, more machines, more stocks of materials. And that means a greater ability to produce and, therefore, a larger supply of goods offered for sale and, consequently, again a tendency toward lower prices, not higher prices.

As I have already shown, the fall in prices that the profit motive has actually achieved is obscured by the fact that prices are expressed in terms of paper money, whose own value falls more rapidly than the profit motive can reduce the prices of goods. This is what is responsible for the rise in prices expressed in terms of paper money.¹⁸ The situation is comparable to selecting a melting ice cube as a unit of volume and then observing that all measurements of volume persistently increase.

What complicates matters and makes the profit-push doctrine appear plausible to many people is that there is a definite *association* between inflation and a high rate of profit. However, it is not, as most people seem to believe, a rising rate of profit that raises the price level, but an expanding quantity of money and growing aggregate demand that increases both the price level and the rate of profit. As I showed in Chapter 16, rising aggregate demand raises the nominal rate of profit. Insofar as the rise in aggregate demand outstrips the rise in production and supply, the rise in the nominal rate of profit is accompanied by a rise in prices. It cannot be stressed too strongly that the rate of profit that is increased is not a genuine rate of *gain*, but merely the rate of profit *as expressed in a depreciating paper money*—that is, it is merely the nominal rate of profit that is raised, not the real rate of profit. The real rate of profit, of course, is the rate that is found after deducting from profits an allowance to cover the loss in the purchasing power of money. Indeed, in a period of inflation the real rate of profit typically *falls*.

We have already seen an excellent illustration of this fact in our discussion of the widespread ignorance and evasions that support price controls, namely, in the case of the hypothetical merchant who buys his goods at the beginning of the year and sells them at the end. We saw how inflation serves to raise the nominal rate of profit of this merchant while simultaneously reducing his after-tax real rate of profit.¹⁹ As I will show later in this chapter, exactly the same situation applies in the case of depreciable assets, such as buildings and machinery.²⁰ Nevertheless, despite the decline in real profits it entails, despite the fact that it is an effect, not a cause of inflation, many people, particularly in politics and in the news media, never tire of blaming rising prices on the rise in the nominal rate of profit and implicitly or explicitly demand that government controls be imposed to limit profits.

5. Critique of the “Crisis-Push” Variant

The “crisis-push” doctrine is the attempt to blame rising prices on some sudden event, such as the Russian wheat deal in 1972, the Arab oil embargo in 1973, or the Iranian revolution in 1979, that reduces the supply and increases the price of some important good or group of goods. The doctrine rests on two basic errors. The first is the assumption that because a crisis can explain a large increase in the price of a particular good, it can explain a correspondingly large increase in the general price level.

A crisis can explain a dramatic increase in the price of the particular good in whose supply it takes place, if the good is a necessity. This is undisputed. For example, a few percent reduction in the supply of wheat or oil can cause a dramatic increase in the price of wheat or oil, as the Russian wheat deal, the Arab embargo/cartel, and the Iranian revolution all clearly showed. The inference drawn from this fact by the supporters of the crisis-push doctrine, however, was that these supply reductions could somehow also explain the less dramatic but nevertheless still very substantial rise in the general consumer price level that was taking place at the same time. That inference was an error.

It was an error because not only does a rise in the price of a necessity not explain a rise in the price of other items, but, as we have seen, it actually tends to make the prices of a whole host of other items *fall*. It has this effect because what makes it possible for people to pay the disproportionately higher price of the necessity undergoing the supply crisis is that they restrict their expenditure for other items. The prices of these other items, therefore, tend to drop. The result is that the overall rise in the general price level is relatively slight—because the dramatic rise in the price of the necessity suffering the supply crisis is largely offset in the average of prices by a mass of other prices that not only do not rise, but many of which actually fall. And because of the widespread declines in prices that would occur, even such rise in the general price level as a supply crisis could achieve would not qualify for description as a case of inflation, for the reasons already explained.²¹

This reasoning applies not only to the case in which the good undergoing the supply crisis is a consumers’ good but also to the case in which the good undergoing the supply crisis is a capital good that itself enters into the production of a large number of other goods as a raw material. In the latter case, the rise in the good’s price does not serve equivalently to raise the cost of production and prices of its various products, as many people appear to believe. On the contrary, the rise in its price places pressure on the prices of other, complementary factors of

production to fall. A reduction in the supply of oil, for example, reduces the utility of such materials as iron, copper, rubber, and so on, and can even make them practically useless. It thus tends to reduce the prices of these raw materials. It also tends to reduce the wage rates of the workers required in the various processes of production that depend on oil. The result is that costs of production do not rise to the same extent as the price of oil, and where such other factors of production whose price has fallen enter into the production of products to a relatively greater extent than oil, costs of production actually tend to be reduced, not increased.

The second error of the crisis-push doctrine is that it confuses what is at most the cause of a transitory, delimited rise in the general price level with the cause of a permanent, repeated, and, indeed, accelerating rise in the general price level. By this, I mean that a crisis is capable of raising the general price level only in the period in which it reduces aggregate supply and only to the extent that it reduces aggregate supply. Thereafter, its ability to raise prices any further is exhausted. Furthermore, almost all supply-crises are subsequently *solved*. At that point, the effect of the restoration of supply should be to reduce the general price level to its former, precrisis level.

For example, the giveaway of a large part of our wheat to the Russians in 1972 could explain some rise in our price level in 1972 and 1973—a rise corresponding to the fall in aggregate supply that was constituted by the fall in the supply of wheat and wheat products. But in 1973 there was no repetition of the wheat deal. Therefore, insofar as it depended on the supply of wheat, by 1974 aggregate supply was restored to its precrisis level. And insofar as the supply of wheat was a factor determining the general price level, the general price level also should have been restored to its former, precrisis level.

It follows that if we want to explain why prices in 1974 were higher than in 1972, we cannot use such a thing as the crisis in the supply of wheat. The principle here is that all crises that end up being solved—and this includes the great majority of them—can be causes only of *temporary* increases in the price level.

To explain a *permanent* rise in the general price level on the basis of supply crises, one must assume that as one crisis is solved, another, of equivalent magnitude, erupts. But if one makes this assumption, one should realize that one cannot then use supply crises to explain a price level that *rises from year to year*. The effect of an annual repetition of more or less equal-sized crises that are later solved cannot be to raise the price level year after year, because the effect of each new crisis on the price level is canceled by the solution of an old crisis. Consequently, the most that could be explained would be a price level

that was higher than it would be in the absence of crises, but not a *rising* price level.

In order to explain a rising price level on the basis of supply crises, one would have to find not only replacement crises for the ones that have been solved, but additional crises as well. And in the next year, one would have to find replacements for this larger number of crises, along with still more additional crises; and this would have to go on from year to year at a compound rate. In order to explain not merely a rising price level, but one that rises with acceleration, one would have to find not only supply crises growing at a compound rate, but growing at an accelerating compound rate. This, of course, would imply the rapid disappearance of material civilization.

In the years to come, because of growing irrationality on the part of the government, it is possible that we will have growing supply crises. But the most that these crises could be responsible for in the way of a rising price level would be on the order of one or two percent a year. Nevertheless, if they come to pass, prices will almost certainly rise far more rapidly—perhaps 50 or 100 percent a year, or more. That is because a major form in which the growing irrationality of the government will manifest itself, assuming it actually does occur, will undoubtedly be an accelerating expansion of the money supply.

The truth is that operating alongside the largely self-canceling phenomenon of the eruption of new crises and the solution of old crises is the expansion in the quantity of money and rise in aggregate demand. It is this which makes the price level rise far more rapidly than could ever be accounted for by an excess of new crises over the solution of old ones.

The root of both errors of the crisis-push doctrine is a failure to think on the conceptual level—a failure to go beyond what is immediately, almost perceptually evident. We have just seen that the second error rests on the failure to extend one's field of observation back to the past and forward to the future—to see that the solution of yesterday's crises should now be acting to reduce the price level—either actually to reduce it, or at least to nullify the ability of today's crises to raise it; and that later on exactly the same point will apply to the solution of today's crises; and thus that the real cause of steadily rising prices must be something other than the transitory and self-canceling element of crises.

The first error is very similar. It consists of the failure to extend one's field of observation sideways, so to speak, to the goods whose supply is not in a state of crisis. This underlies the failure to see that supply crises act to reduce the demand for and the prices of all these other goods, and therefore could simply never account for a

very dramatic rise in the *general* price level, let alone for the phenomenon of almost universally rising prices, which people have in mind when they complain about “inflation.”

6. Critique of the Wage-Price-Spiral Variant

Little can be said in criticism of the wage-price spiral doctrine that has not already been said in criticism of the other variants of the cost-push doctrine. In the absence of an increase in the quantity of money and rising aggregate demand, any “wage-price spiral” that somehow came into existence would quickly burn itself out of existence in mounting unemployment and unsold stocks of goods. Even in cases in which labor unions hold the contractual right to receive wage increases on the basis of cost-of-living increases, they abandon this right when insistence upon it would add still more of their members to the ranks of an already large number of unemployed members. The experience of the early 1980s provides dramatic confirmation of the truth of these propositions.

7. Critique of the “Velocity” Doctrine

While the cost-push doctrines seek to deny the role of rising aggregate demand as the cause of rising prices, other doctrines opposed to the quantity theory of money concede the fact that more demand is responsible for rising prices. What they deny is that an expanding quantity of money is the cause of rising demand. They seek to blame something else for the growth in demand—something that will not leave a trail that runs back to government interference in the economic system.

The most important doctrine in this group is the velocity doctrine, which subsumes all of the other doctrines in the group. The velocity doctrine is the claim that the rise in aggregate demand that is admittedly responsible for the rise in prices is the result, not of an increase in the quantity of money, but of an increase in the velocity of circulation of money. The velocity doctrine has been widely taught at colleges and universities in a deliberate attempt to undercut the quantity theory of money.

To dispose of the velocity doctrine, nothing more is required than to recall the discussion of the demand for money in Chapter 12. There it was established that in the absence of increases in the quantity of money, any rise in velocity resulting from such factors as growing security of property and the development of financial markets and financial institutions would be the accompaniment of a process that increases both the complexity of production, in terms of the number of distinct stages requiring purchases and sales, and the physical ability to produce.²² Both of these factors militate against any loss

in the purchasing power of the monetary unit. The first, it should be realized, militates against a rise in the aggregate demand for *consumers’ goods* taking place as the result of the fall in demand for money, and thus against a rise in the so-called income velocity of money. It implies that the rise in spending takes place primarily or entirely in the purchase of labor services, capital goods, and securities, and thus that the rise in velocity occurs primarily or entirely in broader measures of velocity, above all, in so-called transactions velocity, which is the ratio of spending of all kinds to the quantity of money.

What causes an increase in velocity capable of substantially contributing to an increase in the demand for consumers’ goods and to a rise in prices is precisely *the increase in the quantity of money*. As shown, the more rapidly the quantity of money increases, the less tends to be the demand for money for holding and thus the higher tends to be the velocity of circulation of money. (The reasons, it should be recalled, are four: First, the effect of an expanding quantity of money on the prospect for prices rising and thus being able to gain by buying sooner rather than later. Second, the effect on the prospect for being able to dispose of inventories and other assets easily and profitably. Third, the effect on the prospect for being able to borrow easily and profitably. Finally, the effect of an expanding quantity of money on nominal interest rates, which is to encourage the lending out of short-term funds that it otherwise would not have been worthwhile to lend out.²³) To not only end the rise in velocity, but to bring it crashing down, nothing more is required than to cut back on the rate of increase in the quantity of money on which the rise in velocity rests. To the extent that that is done, all of the factors artificially reducing the demand for money for holding and thereby elevating velocity are removed, with the result that the demand for money for holding is restored and velocity falls correspondingly.

Experience of the last decade provides ready confirmation of this conclusion no less than it does of the ease with which a reduction in the rate of increase in the quantity of money can put an end to “wage push” and all other varieties of “cost push.” Reduction in the rate of increase in the quantity of money both in the early 1980s and then again in 1989 and most of 1990, following years of more rapid rates of increase in the quantity of money, was on the point of so increasing the demand for money for holding and so reducing velocity, that the result both times was a major recession marked by a close approach to the precipice of a major depression. In both cases a plunge in velocity and the onset of a major depression were avoided only by the resumption of a substantially more rapid rate of increase in the quantity of money.

Thus, just as in the case of the wage-push doctrine,

and all the other variants of the cost-push doctrine, the intellectual zone of explanation previously claimed by the velocity doctrine should henceforth be regarded as annexed by the quantity theory of money. For it is the growth in the quantity of money that explains the inflationary rise in the velocity of circulation of money.

It is necessary to anticipate and lay to rest a speculation that could arise concerning the possibility of some form of “cost push” causing an increase in velocity. To understand why cost push cannot have any significant effect on velocity, we need only imagine an arbitrary rise in prices achieved by cost push—say, a 10 percent increase in prices. The reason velocity could not rise is because in order to pay these higher prices, individuals and business firms would need to increase their cash holdings. (For proof, the reader should consider the effect on his need to hold cash if his rent, food bill, and so on were increased by an average of 10 percent. In such a case he would have to hold a correspondingly larger checking balance and carry correspondingly more currency.)

Indeed, the additional need to hold cash may appear to imply that velocity would actually *fall* as the result of a rise in prices caused by cost push. However, this too would be an error. What would actually happen is that some individuals would end up holding more money to make their purchases and pay their bills at higher prices, while other individuals, who would be unemployed, would end up holding less money, in accordance with their loss of income and ability to purchase. Business firms on the average would also end up not needing to hold any more money than previously; they would need to hold more money per unit of the things they bought, in order to pay the higher prices of those things, but, at the same time, they would, on the average, buy fewer units. Thus their need to hold cash in the aggregate would be unchanged.

8. Critique of the “Inflation-Psychology” Doctrine

A leading variant of the velocity doctrine is the “inflation-psychology” doctrine. As used by its supporters, the term “inflation psychology” is supposed to refer to an uncaused primary. That is, people allegedly have an inflation psychology, and that is supposed to be the ultimate cause of inflation. *Why* people have an inflation psychology is a question that is not raised, let alone answered. They simply have it, and because they have it, they spend more rapidly.

Of course, there is such a thing as inflation psychology, but it is not a primary. It is based on the *fact* of inflation. It comes into existence only after many years

of inflation. Properly understood, what the term “inflation psychology” really refers to is the various ways in which a rapidly expanding quantity of money reduces the desire of people to hold money. Properly used, the term embraces the four connections we have traced between an expanding quantity of money and a rising velocity of circulation of money.

Inflation psychology actually refers to more than these connections between an expanding quantity of money and a rising velocity of money. It refers to more, because these connections have an effect on prices only by way of raising aggregate demand. Inflation psychology also has an influence on prices from the side of supply, because it influences the expectations of sellers. For example, if businessmen come to anticipate that in the years ahead inflation will raise the replacement costs of their plant and equipment, they may begin to raise prices today, in order to be in a position to accumulate sufficient replacement funds. Similarly, workers may demand wage increases in advance, in order to cover the rise in prices they expect to occur over the life of their employment contracts. Landlords may demand rent increases to cover the rise in prices and costs they expect to occur over the life of their rental contracts. And lenders may demand interest rates high enough to cover the increase in prices they expect to occur over the life of their loan contracts. These forces cause a rise in prices beyond the levels appropriate to the current size of demand—they make the rise in prices outrun the rise in demand by gearing this year’s prices, in effect, to the expected demand of next year and beyond. These price increases operate as a kind of “cost push,” but, of course, one that is entirely induced by the expansion in the quantity of money and rise in aggregate demand; and they have the same limits as any other price increases coming in the form of cost push—namely, the limits imposed by reductions in the quantity of goods that can be sold and by mounting unemployment.

Because of the widespread belief that inflation is a means of preventing and combatting unemployment and achieving full employment, it cannot be stressed too strongly that when it reaches the stage of inducing sellers to raise prices in advance of the current rise in aggregate demand, its effect is actually to *cause unemployment*. Because insofar as the rise in wages and prices outstrips the rise in demand, the supply of goods that can be sold and the quantity of labor that can be employed must fall.

Now sometimes, when the government makes an effort to cut back on inflation, and really does reduce the rate at which it expands the money supply for a while, some observers, who are familiar with the quantity theory of money, are surprised to see that prices continue to

rise at a substantial rate. And they take this fact as evidence against the quantity theory, claiming that it shows that inflation psychology exists and is leading a life of its own, as it were.

The error in this reasoning is not hard to find. So long as our money is a paper money, that the government can inflate as much as it likes, there is no reason for people to believe that the government will not soon resume a more rapid rate of inflation—especially in view of the fact that the whole philosophy of the mixed economy drives it to do so. In order to convince people that it is serious in its determination to end inflation, the government must restrict its increase in the quantity of money for a protracted period. In the meanwhile, however, because people have had no reason to believe that the government will continue to limit itself, they will probably have placed themselves in even more overextended positions, in which they are operating with even lower money balances, have further increased their borrowings, and are asking still higher wages and prices—all in the expectation that inflation will come to their rescue and provide justification for their action. In this context, stopping the inflation or significantly restricting it must precipitate a crisis. And then the government must either allow the crisis to occur or, to avoid it, give in and fulfill people's expectation that inflation will resume.

It would be a serious mistake to describe this situation by saying that the government is forced to resume inflating in response to the inflation psychology of the people. It is the government's ability to inflate, and its repeated use of that ability in the past, that created the inflation psychology and that makes the consequences of finally stopping the inflation so severe.

This type of situation illustrates an inherent flaw of paper money. The fact that paper money can be inflated, and over time is inflated, causes expectations about future inflation. The existence of these expectations then makes it impossible to stop inflating without a crisis, while the threat of the crisis induces the government to resume and accelerate the inflation. Inflation psychology is an inevitable consequence of paper money and is a critical step in its ultimate downfall.

The events of the 1960s and 1970s in the United States provide clear confirmation of this process. Each time the government attempted to slow down the increase in the quantity of money, a crisis began to develop, and it quickly resumed the increase, and at an accelerated rate. The result was a growing expectation of continued and accelerating inflation. The policy adopted by the U.S. government in the early 1980s, which was carried to the point of producing a very major recession—a depression, according to many—represented the first serious interruption in the process of accelerating inflation since

1933. In 1989 and most of 1990, hardly any increase whatever occurred in the quantity of money. The effect of these two sustained reductions in the rate of increase in the quantity of money was a radical reduction in the amount of inflation psychology that existed. Indeed, the reduction in inflation psychology between 1990 and 1992 was so great that it was possible to discern a growing deflationary psychology.

It should be realized that under a gold standard, inflation psychology could not exist to anywhere near the degree to which it exists under a system of fiat money. This is because under a gold standard, it would have little or no *factual* basis. To the extent such a psychology began to develop, it would quickly run up against the fact that the money supply did not keep up with it, because it simply could not. At that point, the consequence would be that inflation psychology would disappear.

This is true even of a fractional-reserve gold standard. During the phase in which banks are in a position to expand the quantity of money more rapidly than the supply of gold, there is a limited inflation and some degree of inflation psychology develops, at least to the extent of people taking for granted the ability easily and profitably to borrow and to liquidate inventories and other assets in the face of a rising demand. But as soon as it becomes necessary for the banks to limit the rate of increase in the quantity of money to the rate of increase in the supply of gold, or less, in order to rebuild their gold reserves, these aspects of inflation psychology disappear. They are wiped out in the face of a tightening of credit and an unexpectedly low demand for goods and services.

A 100-percent-gold-reserve system would be characterized by the lowest possible degree of inflation psychology, that is, typically, by none whatever. Under such a system, the quantity of money could never increase more rapidly than the supply of gold. Under such a system, the only possible source of something akin to inflation psychology would be unduly rapid increases in the supply of gold itself, which can never occur at anything remotely approaching the rates of increase in the quantity of money achievable under a system of fiat money.²⁴

9. Critique of the Credit-Card Doctrine

A second variant of the velocity doctrine is the credit-card doctrine. The supporters of the credit-card doctrine view credit cards as making possible a rise in spending without any expansion in the quantity of money. They observe, for example, that people who carry credit cards do not need to carry as much currency as previously, and they conclude on this basis that credit cards contribute to

a rise in the velocity of money, by making possible more spending in relation to the same quantity of money.

The first objection to be made to the credit-card doctrine is that much of the reduction it makes possible in the need to hold money is merely apparent, and not real. This is the case insofar as credit cards are actually used in making purchases.

To prove this point, let us consider the case of cards like the American Express card, in which all charges must be paid within a few weeks. The holder of such a card need not carry as much currency in his pocket—that is certainly true. But he must have money to pay his credit-card bill when it comes due. As a result, the money that such an individual is spared from holding in currency, he must hold in his checking account, in order to be able to pay his credit-card bill.

Of course, in some cases, an individual might use his credit card and not immediately set anything aside for the payment of his credit-card bill. For example, he might decide to pay his bill out of his next paycheck, which is not to be received for one or two weeks. Even in these cases, however, it is a mistake to believe that credit cards increase the velocity of circulation. Because while the individual card holder can spend money he does not have, the credit-card company, or the supplier from whom the card holder buys, must be in possession of the necessary funds to pay for his purchases. If the credit-card company must pay the supplier immediately, then what occurs is essentially no different than if the card holder went to the credit-card company, borrowed money and then paid for his purchases with cash. If there is some delay in payment by the credit-card company, then the supplier is placed in the position of having to extend credit. But to be able to do this, he has to obtain additional financing, because while his money revenues temporarily drop, he continues to need just as much money as before to pay his own suppliers and meet his own personal commitments. Thus, he has to borrow correspondingly more; what occurs here is the equivalent of the supplier borrowing money for his customer, which the customer then spends in the supplier's shop. In either case, it is not that the credit-card holder's spending takes place without the existence of money, but that, in effect, he borrows and spends the money of a lender. Total spending in relation to the quantity of money is unchanged in these cases.

Indeed, on the basis of this discussion, we must conclude that particularly in the case of credit cards in which all the charges come due within a short period, it is probably true that the overall need to hold money is *increased* rather than decreased. This is because not only must money still be held to pay for the credit-card holder's purchases but, in addition, as we have seen, the

credit-card holder needs to hold money to pay his credit-card bill when it comes due. Thus, there are now *two* transactions and a need for *two* cash holdings, whereas before there was only one transaction and a need for only one cash holding. Before the existence of credit cards, an individual who went to a restaurant, say, had to carry currency to pay his restaurant bill. Now, equivalent money must be held either by the credit-card company or by the restaurant, to finance his purchase. In addition, the credit-card holder must hold money to pay his credit-card bill when it comes due. Thus, two cash holdings are required in place of one, to effect the same purchase of goods and services. The necessary tendency of such a state of affairs is to reduce the aggregate demand for consumers' goods in relation to the quantity of money. For the situation is one of greater complexity of the productive process, with more stages of buying and selling being present and thus requiring diversion of funds from expenditures for consumers' goods to expenditures at a different stage of transactions.

Conditions are not significantly different in the case of credit cards that can be paid off gradually over many months, like the Visa card or Mastercard. In practice, of course, many people use these cards in just the same way as the American-Express-type card and pay off their credit-card balances in full each month. But insofar as the balances on these cards are paid off in modest amounts over a period of years, the effect is initially to increase the demand for money for holding by less than in the case of the American-Express-type card and then, in all the succeeding months, to increase it by more. In the first month there is a demand for money to finance the purchase of the merchandise plus a modest demand for money to pay the installment on the credit card, instead of a demand for money to finance the purchase of the merchandise plus an equivalent demand for money to pay off the credit-card balance. But in each succeeding month there is a demand for money to pay an installment on the credit-card debt, plus interest, whereas there is no such demand for money in the case of the American-Express-type card.

The aspect in which credit cards do reduce the demand for money for holding is insofar as they are not actually used but merely provide their holders with the potential for use. To this extent, they represent the possession of guaranteed lines of bank credit. That is, whoever has such a card has the right to borrow up to some agreed-upon sum to be provided by the banks involved, any time he wishes. And to this extent, credit cards can in fact reduce the amount of money that people need to hold to some degree. They do so in cases in which a person was previously holding money on the chance that he might come across something he wanted to buy and was uncer-

tain that he would be able to obtain a loan to buy it. Such a person need not hold that money now. His loan is guaranteed in advance by virtue of his possession of the credit card and the line of credit it conveys.

But now we must ask how it happened that the banks could extend lines of credit to people who previously would have been uncertain of being able to obtain loans for specific purposes. The answer to this question brings us back once again to the quantity theory of money. The banks can extend additional lines of credit because they are in a position to expand the money supply by creating checking deposits that they can lend out. Thus, what we are dealing with in this case is nothing but the influence of an expanding money supply on the availability of credit and the demand for money. We have already seen how the increase in the quantity of money entering the economic system in this way operates to reduce the demand for money. The existence of credit cards based on this foundation means merely that the ability of the banks to expand the money supply enables consumers as well as business enterprises to attempt to reduce their holdings of money, with the same effect on the velocity of money. Thus, to the extent that credit cards do in fact raise velocity, the rise must be considered merely a further symptom of the expanding quantity of money.

The objection might be raised that even without the banks' ability to create money, credit cards would still have come into existence and might still have reduced the need to hold money on the part of the holders of the cards. That is probably true to some extent. But in the absence of the banks' ability to inflate, the extension of additional lines of credit would be strictly limited, and the only way that the banks could extend additional lines of credit at all—whether to consumers holding credit cards or to any other type of borrower—would be as a result of the availability of the necessary *savings*.

These savings could only become available either as the result of the withdrawal of savings from other uses, or as the result of an increase in the overall supply of savings. Either way, if the base of the additional lines of credit is savings, then what is presupposed at the very beginning is a corresponding reduction in spending somewhere else in the economic system. That is, either spending financed by the use of savings will be less somewhere else or, if the overall supply of savings available for use is increased, consumer demand will be less, because the existence of the additional savings is possible only to the degree that people consume less. Lines of credit based on savings, therefore, cannot be presumed to raise the overall volume of spending, because the origin of such lines of credit is a *reduction* in spending somewhere else in the economic system.

10. Critique of the Consumer-Installment-Credit Doctrine

Still another variant of the velocity doctrine is the doctrine of consumer-installment credit. According to this doctrine, prices rise because the granting of consumer-installment credit enables consumers to make an additional demand for goods.

Here, consistent with the principles presented in the preceding section, it is necessary to realize that the granting of credit out of savings represents merely a transfer of spending power from some parties to others. The savers must first reduce their consumption. Only then can the savings exist that are made available to borrowers. Or if the savings already exist and are being used, they can be made available for a new use only to the extent that a previous use is curtailed. There is no increase in overall spending whatever, but merely offsetting changes in the extent of particular types of spending, as the result of the granting of credit out of savings. To state the matter as succinctly as possible: credit granted out of savings is not inflationary. Only credit based on the ability to expand the money supply is inflationary.

The installment-credit doctrine is true only to the extent that the credit is granted out of newly created money. It is false to the extent that the credit is granted out of saved funds. Because to the extent that consumers obtain credit out of saved funds, the savers have first had to restrict their consumption before the consumer-borrowers can expand theirs, or some other set of users of the savings has had to restrict its spending. There is no increase in overall spending here, but just a transfer of spending power from one set of buyers to another.

Consequently, once again, an opposing doctrine turns out to confirm the quantity theory of money. For the only way the installment-credit doctrine could possess an element of truth is on the basis of an expanding quantity of money.

The same principle applies to every form of credit: credit granted out of savings is not inflationary. Only credit granted out of newly created money is inflationary.

This principle also applies to every form of debt. The incurrence of debt in and of itself is not inflationary. Debts incurred through the borrowing of savings are not inflationary. Only debts incurred through the borrowing of newly created money are inflationary. When applied to government budget deficits, this means that deficits financed by borrowing from the public—i.e., through the sale of securities to individuals and business firms—are not inflationary (which, of course, is not to say that they do not have other highly destructive consequences²⁵). Only deficits financed by the creation of new and additional money are inflationary.

11. Critique of the Consumer-Greed Doctrine

The claim is sometimes made that inflation is the result of the consumers' "greed." Occasionally, it is the consumers' mere desire for a better life that is named as the cause of inflation, and in those very words.

The supporters of the consumer-greed doctrine appear to have in mind a case in which the consumers simply go out and overbid one another in their desire for more goods. It is possible that the supporters of the doctrine have in mind the scene of an auction in which the bidders scramble for a limited number of items and drive prices to high levels in their enthusiasm.

Such action on the part of consumers could explain how the price of a few items might rise. But it cannot explain how the general price level rises. It cannot, because it does not tell us where the consumers obtain the money to start spending more for everything. If the consumers do not have more money available in toto, then they can bid up the prices of some things only by correspondingly reducing their purchases of other things. But that implies that the prices of these other things tend to fall. No problem of inflation would exist, therefore. Nor is it reasonable to assume that "greed" somehow leads the consumers to reduce their demand for money for holding. Indeed, the only thing that could make such behavior the "greedy" thing to do, rather than continuing to maintain the same demand for money as before, would be if the quantity of money is rapidly increasing, which would provide real incentives for a drop in the demand for money. But this, of course, brings us back once again to the quantity theory of money.

Finally, it should be realized that what the consumer-greed doctrine actually cites as the cause of higher prices is people's desire for a higher standard of living. That is the meaning of their "greed." Not only is this not a cause of higher prices, but, in reality, it is the cause of *lower* prices. Because what people must do to raise their standard of living is *produce more* and *save more*. This is exactly what everyone tries to do who is seriously interested in improving his standard of living. Thus, his "greed" is the source not of more spending out of nowhere, but of harder work, more forethought and provision for the future, and thus more production and supply and therefore lower, not higher, prices.

12. The Meaning of Inflation

The preceding discussions of explanations of rising prices other than the quantity theory of money, have served further to confirm the quantity theory of money.

It has been shown that insofar as the alternative explanations contain any kernel of validity at all, it is only as an extension of the quantity theory of money. The increase in the quantity of money and the consequent rise in aggregate demand is what underlies any ability of labor unions to engage in "wage push," of businessmen to engage in "profit push," of crises to be accompanied by a general and sustained rise in prices, and of the velocity of circulation to rise in circumstances that are accompanied by rising prices. It is what underlies the existence of all so-called wage-price spirals, of "inflation psychology," and of any inflationary consequences that can be associated with the use of credit cards, installment credit, or any other form of credit, or with consumer "greed." Thus, the quantity theory of money rightfully annexes, as it were, the explanatory territory previously claimed by all these opposing theories.

The undue increase in the quantity of money that underlies the rise in prices has, moreover, been shown to be the responsibility of the government. The moneys chosen by the market were, and would be again, gold and silver. These moneys do not increase at a rate sufficient to cause a sustained significant rise in prices. Even what was probably the greatest percentage increase in the supply of these metals in recorded history, which took place in consequence of the Spanish conquest of the New World, was not sufficient to raise prices in Europe by much more than an average of 1 percent per year over the course of the next two centuries. Indeed, for long periods of time, gold and silver are capable of increasing at a lesser rate than the increase in the supply of goods and services in general, and thus, when they serve as money, of being accompanied by falling prices—as was the case in the generation prior to the discovery of the California gold fields in 1848 and in the generation from 1873 to 1896.

It was government interference over a period of more than two centuries that brought about the abandonment of the use of gold and silver as money and thus of the powerful restraint on the increase in the quantity of money that a gold or silver money entails. In the last sixty years or more, the government of the United States, like that of virtually every other country, has had unlimited power to expand the quantity of fiat paper money and has made ample use of that power.²⁶ Thus, the whole problem of an inflationary rise in prices reduces to an increase in the quantity of money at a rate more rapid than the increase in the supply of gold and silver or, to what is equivalent in view of its role in their abandonment as money, an increase in the quantity of money caused by the government.

All of the knowledge concerning the cause of rising prices presented so far in this chapter and in Chapter 12,

can be summarized in a definition of inflation as, precisely, *an increase in the quantity of money more rapid than the increase in the supply of gold and silver*, which is to say, *an increase in the quantity of money caused by the government.*²⁷

This is a definition in terms of fundamental causation, and one which explains *all* of the major symptoms of inflation: namely, a sustained significant rise in prices, a rise not only in the general price level but in the whole range of prices, debtors being enriched at the expense of creditors, high nominal profit and interest rates, and a low demand for money for holding, among others.

This definition, moreover, shows how to stop inflation: namely, stop the government from creating or sponsoring the creation of money in excess of gold and silver—viz., force the government to reestablish, and/or allow the market to reestablish, the gold and silver monetary system that the government has destroyed. This will put an end to inflation and all of its symptoms.

In sharpest contrast, the usual definition of inflation that is offered, which is “rising prices,” provides no knowledge of causation. As I have shown, it perpetuates ignorance and confusion by making it possible for a wide variety of things to appear as possible causes of inflation, thereby making it impossible to be confident of the explanation in any given case. Furthermore, the definition of inflation as rising prices implies that businessmen are always the parties directly responsible for inflation, since they are the ones who decide such things as whether or not prices posted on store shelves or listed in catalogues are to be increased. And, of course, the definition of inflation as rising prices supports the corollary belief that inflation can be remedied by price-and-wage controls, since, according to it, the absence of price and wage increases that can result from such controls means the absence of inflation.²⁸

Ironically, the definition of inflation as rising prices serves actually to promote inflation. It does so in part by implying that price controls are the remedy for inflation. For once price controls are enacted, the government feels free to inflate the money supply all the more rapidly, in the mistaken belief that merely because prices cannot rise, it does not have to worry about inflation—as though because the symptom was gone, the underlying cause of the symptom was also gone. The definition of inflation as rising prices also serves to promote inflation by suggesting government subsidies to keep down prices, which subsidies are likely to be financed by creating still more money. Thus, for example, in believing that it reduces inflation by keeping down the price of bread and milk, say, by means of paying subsidies to cover the losses entailed in their sale at artificially low prices, the gov-

ernment may very well be led to increase the quantity of money more rapidly, in order to obtain the funds with which to pay these subsidies. In this way, the government resorts to more inflation in order to fight a symptom of inflation.²⁹ Probably the leading instance of this bizarre practice is the pursuit of a so-called easy-money policy for the purpose of holding down interest rates. High interest rates are mistakenly believed to be a cause of rising prices, rather than the effect of the rapid increase in the quantity of money. The result of such ignorance concerning inflation is that the increase in the quantity of money is made still more rapid, for the purpose of keeping down interest rates.

In addition, the definition of inflation as rising prices makes no distinction between higher prices which are the result of more demand or of less supply. And thus it perpetuates the confusion that things which cause less supply are responsible for inflation. Finally, this definition is incapable of contributing anything whatever to the explanation of symptoms of inflation other than the rise in the general consumer price level—for example, such symptoms as a rise in the whole range of prices, debtors being enriched at the expense of creditors, high nominal profit and interest rates, and a low demand for money for holding.

The importance of determining which of these two contending definitions of inflation—rising prices or an increase in the quantity of money more rapid than the increase in precious metals—is the proper one, cannot be overestimated. The difference between them is as important as the difference between holding a right or a wrong understanding of a disease—of knowing what it is that causes all the symptoms of the disease and what needs to be dealt with to eliminate the source of the symptoms, versus attempting to deal directly with an isolated symptom. Thinking of inflation as being nothing more than rising prices is comparable to thinking of a disease as consisting of nothing more than a high temperature reading, say, which would imply that the remedy is as simple and as absurd as packing the thermometer employed to take the temperature in ice—a remedy that would be on the same intellectual level as imposing price controls as the cure for inflation. It is comparable to thinking that a problem of excessive pressure in a boiler is merely one of movement of the pressure gauge and that the pressure can be brought down by forcing the gauge to a lower reading—another solution on the intellectual level of the enactment of price controls.

Correctly understanding the meaning of inflation—that is, in terms of an increase in the quantity of money—makes it possible to realize that inflation can be present without the appearance of any of its obvious symptoms,

just as a disease, such as cancer, can be present prior to the appearance of any of its obvious symptoms, and that inflation continues to be present even though some particular leading symptom, such as rising prices, has been suppressed.

Of no less importance is the fact that a correct understanding of what inflation is, makes it possible to raise questions about the causes and consequences of inflation that would otherwise simply be impossible to raise, because one would still be bogged down in trying to determine the cause and consequences of rising prices in a given case. When one has finally thoroughly investigated the causes of rising prices, as we have done, and arrived at the definitive knowledge that only an increase in the quantity of money, specifically an increase more rapid than the increase in the supply of gold and silver—an increase caused by the government—can qualify as an explanation that is consistent with all of the facts, one is able to raise questions pertaining to whole new vistas of causes and effects.

For example, in the next part of this chapter, in asking the question of what are the causes of inflation, we no longer ask the question of what are the causes of rising prices. We now, once and for all, already know the answer to that question. It is cemented and conveyed in the proper definition of inflation. Thus, in asking what are the causes of inflation, we now go further and ask: *What are the causes of the increase in the quantity of money at a rate more rapid than the increase in gold and silver? Namely, what leads the government to bring about such an increase in the quantity of money?* When it is understood that inflation is, in fact, fundamentally a government policy, not a phenomenon of prices, the question of causation is pushed back to the plane of the intellectual and ideological influences acting on the government when it pursues that policy, and on the citizenry when it supports or calls for the government's policy of inflation.

Similarly, in asking about the consequences of inflation, we are no longer limited to asking about the consequences of rising prices. We can raise questions about *all* the consequences of the undue increase in the quantity of money. These consequences go far beyond rising prices and must be understood if one is to understand the effects of inflation, including the effects of the rising prices inflation causes.

In sum, on the basis of a sound definition of inflation, one is led to ask much more fundamental, wider, and better questions. On the basis of this foundation, it is now possible to turn to a discussion of what I have titled "the deeper roots and further effects of inflation."

PART B

THE DEEPER ROOTS AND FURTHER EFFECTS OF INFLATION

1. The Connection Between Inflation and Government Budget Deficits

Inflation as a government policy is intimately connected with deficits in the government's budget. It is not the case that deficits in and of themselves are inflationary, as is often claimed. If they are financed by selling bonds to the "public"—that is, to private individuals and nonbank corporations—there is no increase in the quantity of money or in aggregate demand. There is merely a diversion of demand: the government spends instead of private borrowers, who are deprived of the funds the government borrows and who must therefore spend correspondingly less.³⁰

Indeed, under a gold standard, deficits financed by borrowing from the public can actually be deflationary, by virtue of threatening government bankruptcy and accompanying political instability, as was shown in the critique of Keynesian policies in the preceding chapter.³¹ These consequences increase the demand for money for holding, cause the export of gold, and threaten the solvency of the banking system insofar as the banks hold government securities as an asset backing fiduciary media. The fact that under a gold standard deficits represent an equivalent drain of savings away from private borrowers, who, for the most part, would have used the savings for the purpose of capital investment, means that they also result in diminished economic progress and, indeed, if practiced on a sufficiently large scale, in the outright economic decline of the country. These destructive tendencies are reinforced by the increase in tax burdens to finance the growing burden of interest and principal payments entailed in a policy of deficits. As a result, the country's relative position in world commerce is impaired, which, if severe enough, also contributes to a decline in the quantity of money that circulates within its borders.³²

What makes government deficits inflationary is *the ability to finance them by the creation of new and additional money*. When they are financed in this manner, the government can spend more and the citizens need not spend any less. Indeed, very soon—once the new and additional money begins to reach them—the citizens too begin to increase their spending. The increase in the quantity of money works its way through the economic system, and as it continues, spending increases in more and more areas, until it rises virtually everywhere. It goes

on rising so long as the deficits are financed by means of the creation of new and additional money.³³

The ability to finance peacetime deficits by means of the creation of new and additional money has existed in the United States since the abandonment of the domestically convertible gold standard in 1933. Prior to that time, the U.S. government was obliged to redeem paper dollars on demand at the rate of one ounce of gold for every \$20.67 of paper. The dollars could be redeemed by anyone, including American citizens. In addition, gold reserves of at least 25 percent against National Bank notes, Federal Reserve notes, and Federal Reserve deposit liabilities were mandated by law. These requirements sharply limited the government's ability to expand the supply of currency and bank reserves and correspondingly limited the ability of the commercial banking system to increase the supply of fiduciary media. In such circumstances, it was simply impossible to rely on the creation of money as the means of financing budget deficits. This was because of an impending deficiency of gold reserves. The deficiency of gold reserves would come about by virtue both of an absolute loss of gold reserves in redemptions of paper money for gold and an increase in the amount of money against which reserves were required to be held.³⁴

Even though from 1933 to 1965 the United States retained substantial gold-reserve requirements against Federal Reserve notes and deposit liabilities, these requirements ceased to be effective once the government increased the official price of gold to \$35 per ounce and thereby increased its gold reserve by almost 75 percent overnight. And then, from the late 1930s until 1945, the U.S. government came into possession of a vast portion of the rest of the world's monetary gold, as many nations used their gold reserves to buy American supplies. As a result, over almost all of this period, the U.S. government was able to create additional paper money as rapidly as it wished, without being limited by a deficiency of gold reserves. When the problem of a deficiency of gold reserves began to develop—as the result of more than a decade of substantial losses of gold reserves in the London gold market and the growing gold-reserve requirements accompanying the increased quantity of Federal Reserve notes and deposit liabilities outstanding—the gold-reserve requirements were simply abolished, and, not long thereafter, the policy of holding the price of gold at \$35 per ounce, as well.³⁵

Prior to 1933, the government did finance wartime deficits by means of creating money. But it had to resort to extraordinary measures in order to do so. To be able to create money for the financing of deficits in the Civil War, it abandoned the requirement of convertibility to gold and issued irredeemable greenbacks. It also estab-

lished the National Banking System with its National Bank notes, which made possible an increase in the quantity of money in the economic system relative to the amount of gold, as National Bank notes, backed 25 percent by gold, came to be used in place of gold coin. In World War I, the government required the banks to turn over their gold reserves to the Federal Reserve System, and to count as their reserves equivalent checking-deposit balances with the Federal Reserve System. The Federal Reserve System then used this gold to support a multiple expansion in its own notes and deposit liabilities, on the basis of which the banking system was able to expand the supply of fiduciary media correspondingly.³⁶

The ability to finance deficits by means of inflation exists today at the federal-government level, but not at the state- or local-government level. Hence only federal deficits can be inflationary. And inasmuch as state and local governments lack the ability to inflate the money supply to finance their deficits, they almost always choose to pursue a policy of balanced budgets—with all of their expenditures financed by current tax revenues. They recognize, implicitly at least, that given their inability to create money to pay their creditors, a policy of deficits on their part would result in bankruptcy. To adopt a policy of deficits, a state or local government must be reckless, corrupt, or ignorant to a very high degree. The government of New York City, which came to the edge of bankruptcy in the mid-1970s before being rescued by the state and federal government, provides the only recent significant example of such a local government.

The mechanism of creating money in order to finance deficits has already been explained. It is the purchase of government securities by the Federal Reserve System, which is accompanied by the creation of new and additional checking deposits for the Treasury. When recipients of the new and additional money spent by the Treasury make additional deposits in their checking accounts, the result is additional standard money reserves for the banking system.³⁷ On the basis of its additional reserves, the banking system in turn can expand the supply of fiduciary media and thereby provide the Treasury with still more new and additional money to spend. (The same state of affairs exists in foreign countries. All one need do is substitute for the Federal Reserve System the name of the appropriate foreign central bank.)

The ability to create money makes it impossible for the federal government to go bankrupt in the technical sense of lacking the dollars required to pay its creditors. So long as what it owes is dollars, and it has the power to create new and additional dollars, it will always have money available to pay its debts. The fact that in the technical sense the government cannot go bankrupt un-

der these conditions, no matter how large its debt becomes, should not be at all surprising. An individual citizen would never go bankrupt either, no matter how much debt he incurred, if he owned a printing press and, whenever the need arose, could just go and run off whatever dollars his creditors required. Precisely this is the position of the federal government under our present fiat-money standard.

Furthermore, an important consequence of the government's creation of money is an increase in its tax revenues, for the money incomes of the citizens are increased by the inflation, and additional taxes are paid on those incomes and on the additional consumer spending that takes place out of those incomes. Indeed, the increase in taxes is almost certain to be more than proportional to the increase in real incomes. This is both because of the progressive nature of the income tax, and thus of the fact that people are pushed into higher brackets and have to pay higher rates of income tax as inflation raises their incomes, and because of the fact that inflation leads to a systematic overstatement of income subject to taxation. Under current federal tax legislation, the upward drift of taxpayers into higher brackets supposedly no longer takes place, since the upper borders of the brackets are supposed to be increased corresponding to the rise in prices each year. After decades, it is welcome to observe some remedy enacted for an obvious abuse. As we will see, however, the more serious problem of the systematic overstatement of income subject to taxation has yet to be addressed.³⁸

Although, given its ability to inflate the money supply, the government can no longer go bankrupt in the technical sense of lacking the money necessary to pay its bills, it has probably long since been bankrupt in the sense of being unable to repay its debt *in the same purchasing power in which the debt was contracted*. The present national debt is the sum of the deficits contracted over all of the years since the administration of President Andrew Jackson, when, briefly, there was no national debt. Repayment of the debt in the same purchasing power in which it was contracted would require restating the debt as the sum of the deficits of all the intervening years, with each year's deficit *adjusted for the rise in prices* between its incurrence and the present. Thus, the portions of the debt which date from the First and Second World Wars would have to be adjusted upwards by a percentage that was equal to the rise in prices since those times, and similarly with the portions of the debt contracted in the 1950s, 1960s, and 1970s. Such an adjustment, of course, would result in a restatement of the debt at a substantially higher level than its already very high level.

It is extremely unlikely that such a restated debt could

ever be repaid. The government would not be able to repay it through inflation, because the more it inflated, the higher would prices rise and the higher therefore would be the restatement of the debt. It is extremely unlikely that even the present national debt, let alone one restated at the substantially higher level necessary to compensate for the loss in the purchasing power of money, can ever be repaid out of taxation. Thus, in real terms—in terms of the ability to repay creditors in the same purchasing power in which they lent—the government is probably bankrupt, and probably has been for many years. For decades, the government has been paying principal and interest in money of substantially lower purchasing power than existed at the time it borrowed the money in question.

The fact that the present national debt is probably beyond the point of any possible repayment in terms of the buying power of the money lent to the government, or even in terms of the present, already sharply reduced buying power of money, may very well help to explain the prevailing high interest rates on long-term government securities—interest rates which for some years have substantially exceeded the rate at which prices have been rising. The height of these interest rates does not have to be explained merely by reference to the likelihood of a reacceleration of inflation and rising prices. Even without such reacceleration, high interest rates on government securities would have to exist to reflect the likelihood that the government is simply unable to repay its current level of debt in real terms, with or without inflation. Interest rates may be high in order to provide a risk premium as well as an inflation premium.³⁹

If this description of matters is correct, then it may be only a relatively short step from the present situation to one in which it is impossible to sell long-term government securities to any buyer *but the government itself*—viz., the Federal Reserve System and the Social Security Trust Funds. For private individuals and businesses will simply stop buying such securities when they conclude that, no matter what happens, they must lose by doing so. Such a result would imply a quantum jump in inflation, because then both the entire annual deficit and the redemptions of government securities coming due would have to be financed almost entirely by inflation.

Budget Deficits and the Monetary Unit

The fact that the government has the power to inflate the money supply means, of course, that government spending is not constrained by tax revenues. In the absence of this power, it would be constrained by tax revenues, precisely because a policy of deficits would drive the government into visible bankruptcy. To avoid this specter, any semiresponsible, representative govern-

ment would make a balanced budget a fundamental principle of its operation, just as almost all state and local governments in the United States do. Any federal administration that failed to do so, would soon be turned out of office.

The implication of these facts is that what is required to put an end to the present policy of deficits is to *deprive the government of the power to inflate the money supply*. Until that is done, all talk about balancing the federal budget is just so many empty words. The talk that comes from the government itself is comparable to a New Year's resolution to reduce his use of credit cards in the year ahead that is made by someone who has a license to counterfeit and thus can have no problem obtaining the money necessary to pay whatever credit card charges he runs up. When all the government has to do to pay its bills is to go and print more money, even proposals for constitutionally balanced budgets cannot be taken seriously. They have no more binding quality than written New Year's resolutions.⁴⁰

The only thing that will ever force the federal government to balance its budget is if it loses the power to create money, and thus is put in a position in which the money it spends must be obtained from the citizens. That will happen only when the monetary unit of the country becomes something that is physically incapable of being produced at a profit except in very limited quantity, and even then probably not by the government, with all of its bureaucratic inefficiencies. That is to say, the monetary unit must be something whose cost of production is usually almost as great as its own value and, in the face of efforts to increase its production, soon rises as high and even higher than its own value. Gold and silver are monetary units of precisely this description.

When they are the monetary units, the government is *physically* deprived of the ability to enlarge the money supply beyond the rate at which a free market would enlarge it, unless it wishes to incur a financial loss and thus defeat all purpose it might have in seeking the enlargement of the money supply.⁴¹ Thus, with gold and silver as the monetary units, the government is made dependent on the taxpayers for every dollar it spends, and is faced with the fact that every additional dollar it wishes to spend must be obtained from the taxpayers. As a result, the government simply does not have the money for spending proposals it would like to implement. It is compelled to reject proposals for a sheer lack of funds, or because their implementation would compel it to abandon other activities it considers more important. No longer is the mere "desirability" of a program a sufficient basis for its adoption. No longer can the government proceed under the delusion that its spending enriches the citizenry.

2. The Motives and Rationale for Deficits and Inflation

The Welfare State

The roots of inflation begin to become clear when it is realized that inflation is desired in large part precisely in order to make possible a policy of continuous budget deficits. Deficits, and the inflation to finance them, are the cornerstone of the welfare state. They are indispensable in order to lend the appearance of reality to the belief that the government is the source of free benefits, which belief is the fundamental delusion underlying the welfare state.

Because the government has the ability to inflate, it can pay for welfare-state programs without having to collect corresponding taxes, and without having to fear driving itself into bankruptcy. On this basis, demagogic politicians have been able to lead people to think of government programs almost exclusively in terms of their alleged benefits, with virtually no regard for their cost. They have been able to depict the alleged benefits of one government program after another—social security, public housing, farm subsidies, rent subsidies, food stamps, foreign aid, aid to education, support of the arts, support of scientific research, Medicare, Medicaid, child care, and on and on—as though no cost were involved. At each step, the demagogues have been able to depict the opponents of such measures as mere curmudgeons, motivated by sheer ill will toward the mass of mankind. For if the programs really were free, there could be no other motive for opposing them.

Thus, the ability to inflate is highly valued—in effect, to enable adults to believe that the government is Santa Claus.

The effect of this delusion, of course, as we have already seen, is a radical expansion in the size of the government.⁴² The popularity and implementation of additional government programs would be far less if it were necessary to finance every additional dollar of government spending with an additional dollar of taxes, as would be the case if the government lacked the power to inflate and thus had to expect bankruptcy as the price of deficits. Then, every time a new measure was proposed, its supporters would be obliged at the same time to explain how its cost was to be paid. Welfare-state programs would cease to appear as free. Rather, they would be perceived as the direct, immediate cause of higher taxes. In such circumstances, the welfare state could not exist.

As matters stand, the supporters of the welfare state are actually able to use the cost of welfare-state projects as the basis for still more government intervention. The

rise in prices that results from the increase in the quantity of money to finance the welfare state, is not perceived as emanating from this cause, but from the greed of businessmen. The welfare state continues to be perceived as the source of free benefits and, alongside of it, businessmen are perceived as the cause of gratuitous evil, with their quest for profits causing the impoverishment of the poor, who must pay ever higher prices. The solutions advanced are that the government must provide still more free benefits, in the form of more and larger welfare-state programs, and—sooner or later—that it must control the prices charged by the evil businessmen, so that the free benefits provided by the wonderful welfare state are not offset by the gratuitous harm the evil businessmen inflict.

Inflation and War Finance

The ability to inflate is also valued because it makes it possible for the government to finance wars which it would not be politically possible to finance through taxation. In effect, it fosters the delusion that, like the welfare state, wars can be carried on without cost. Indeed, because of their being financed by means of inflation, people are actually led to believe that wars are a source of prosperity—because everyone earns more money during a war.

Needless to say, in lending the appearance of reality to these beliefs, the ability to inflate contributes to a greater frequency and duration of wars. In the absence of the ability to finance wars by means of inflation, the prospect of war would be regarded with a dread of its financial and economic consequences no less than of its consequences for human life—because war would then be a time of sharply higher taxes and no increase in money incomes.

Inflation and the “Easy Money” Doctrine

A further root of inflation is the belief that inflation in the form of credit expansion is a means of creating capital and lowering interest rates. If new money is created by the banking system and made available as new and additional loans, then, many businessmen believe, the supply of loanable capital is enlarged and interest rates will fall.

Although held by many of the most eminent and productive members of the economic system, past as well as present, this belief is no less naïve than those of the typical supporters of the welfare state. In fact, it can be described as the businessman’s version of the welfare state, in that it too implies the existence of something for nothing.

As will be shown later in the present chapter, the actual consequence of inflation and credit expansion is not more capital but less, and, along with the undermining of capital formation, the scourge of depressions.⁴³

Inflation as the Alleged Cure for Unemployment

Probably the most important single root of the policy of inflation in the present day is the belief that inflation is necessary in order to prevent or combat mass unemployment. This notion is implicit in the fallacy that falling prices caused by increased production constitute deflation and thus cause depression and unemployment.⁴⁴ On this basis, one is easily led to conclude that steps must be taken to be sure that the quantity of money increases more rapidly—at least to the point of achieving a stable level of prices.

The present-day popularity of the belief that inflation is necessary to deal with unemployment stems, of course, from Keynes, and in the form given it by Keynes this belief powerfully reinforces the other motivations for inflation. The Keynesian doctrine, of course, claims that government budget deficits reduce unemployment and increase output in the economic system by a multiple of the deficits. The additional output of the reemployed workers, which allegedly could not be obtained by any other means, provides not only for the government programs but for much more besides. On this basis, additional government spending supposedly not only costs people nothing, but actually enriches them. In effect, the Keynesian doctrine claims not only that there really is such a thing as a free lunch—paid for by reemployment—but that in people’s efforts to obtain it, they obtain a free breakfast and free dinner as well—namely, the benefit of the additional employment and output that is supposedly “multiplied into being” by virtue of the additional government spending.⁴⁵

The errors of the Keynesian system have already been demonstrated, and it should already be clear why inflation is not required to prevent or combat unemployment—indeed, is incapable of doing so—and why, in fact, what is required is a free market in labor and a monetary system based on the principle of 100-percent-gold-and-silver reserves.⁴⁶ Previous discussion has also indicated how in setting the stage for financial contractions and depressions, inflation is actually the leading underlying *cause* of mass unemployment.⁴⁷ Subsequent discussion in the present chapter will confirm this fact and show how inflation is a preventive or remedy for unemployment only in the peculiar sense that more drugs are a preventive or remedy for withdrawal symptoms.⁴⁸

The Underlying Influence of the Socialist Ideology

If matters are explored at a still deeper level, the pervasive influence of the socialist ideology becomes apparent in the support for inflation.

The expansion in government functions and powers entailed in the growth of the welfare state is a major step toward the establishment of socialism. Both the welfare

state and socialism itself are advocated in the name of the alleged helplessness of the average individual and the alleged omniscience and omnipotence of the State. Inflation creates the appearance of just such a relationship between the individual and the State: on the one side stands the individual with his unmet needs, and on the other side, the State, with funds not derived from individuals, but miraculously created outside the economic system, out of thin air. Thus, it becomes possible through inflation to perceive the State in actual practice in accordance with the socialists' fundamental view of it as an all-powerful, merciful, and redeeming Father. Moreover, the advocates of socialism are none too scrupulous in their respect for individual rights (most obviously, but not limited to, property rights) nor, therefore, in the means they are willing to employ to achieve their ends. The Communists, of course, are openly willing to employ force and violence. Less extreme advocates of socialism, it seems, do not scruple to employ the deceptions of inflation to achieve their goals. Perhaps they deceive themselves as much as the voters, for inflation enables them no less than the public to perceive the State as a kindly Father who provides free benefits.

And, of course, in judging the relationship between inflation and the influence of socialism, one should not forget the famous statement attributed to Lenin, that inflation is the surest method of destroying capitalism. Its possible advocacy on this basis too should not be overlooked.

Although it predates the socialist ideology, the "easy money" doctrine is also promoted by its influence. It shares with the socialist ideology the essential conviction that free benefits can be obtained—this time, not in the form of ordinary benefits from the welfare state for ordinary helpless individuals, but in the form of the allegedly costless creation of additional capital and a lower rate of interest for helpless, needy businessmen, who otherwise could not obtain capital. Furthermore, in the hands of Keynes, the logic of the easy money doctrine was pushed to its limits and was thereby transformed into a vehicle for the virtual abolition of profit and interest income. This was Keynes's doctrine of the "euthanasia of the rentier," which was designed to achieve the goals of Marxism without the necessity of a revolution.⁴⁹

Finally, the belief that inflation is necessary to prevent or combat unemployment is largely an indirect result of the influence of the socialist ideology. This is because the labor legislation and other government interference that creates the problem of mass unemployment in the first place is the result of the influence of the Marxian exploitation theory. In addition, the influence of the exploitation theory prevents any consideration from being given to the possibility that unemployment could be eliminated

by means of establishing the freedom of competition in the labor market, so that wage rates would be free to fall. According to the exploitation theory, freedom of competition in the labor market makes possible the exploitation of labor. With the possibility of free competition in the labor market apparently ruled out, inflation and government spending are made to appear as the only means available for solving the problem.

3. Inflation and Deficits Versus Representative Government and Economic Freedom

Since the time of Adam Smith, a fundamental conflict has been perceived between government budget deficits and the consequent accumulation of a national debt, on the one side, and the institution of representative government, on the other. Deficits oblige future generations to pay taxes for the payment of principal and interest on a debt neither they nor their representatives have any role in incurring and which their representatives cannot be present to oppose. Deficits deprive them of all choice and even voice in a matter for which they will later be held responsible. At the same time, deficits and the accumulation of a national debt are accompanied by the rise of a class of public annuitants—the purchasers of the government's securities—whose investments are guaranteed by the government and who are supported out of tax revenues, irrespective of the fact that those whose taxes must pay their incomes may well not derive even the slightest benefit from the support they must pay.

Even wars should not be financed in this manner, Adam Smith argued, because while the effect may be to make wartime taxes less than they would otherwise have been, the further effect is to encourage and prolong wars and to shorten the periods of peace and capital accumulation. The ultimate effect, Smith pointed out, is that peacetime taxes become as high as wartime taxes would have been without resort to deficits.⁵⁰

Everywhere, the effect of deficits and the accumulation of a national debt, Smith held, is to enfeeble countries, by diverting savings from capital accumulation to consumption and by creating a need for higher and more onerous taxes later on to pay principal and interest—taxes that destroy the incentives to produce and the ability to save, and lay the citizens under a yoke of oppression, in the manner of the Spain of his day.⁵¹ (If one thinks of the nooks and crannies into which the eager hands of the Internal Revenue Service now extend, under the pressure of our own deficits, it is easy to think that Smith was writing of our time.) And ultimately, once national debts reach a certain size, Smith pointed out, they are never fairly and fully repaid. The only release from their burden, he showed, is a government bank-

ruptcy, either open and avowed or in the form of a pretended payment in depreciated currency.⁵²

When the government has the power to inflate and deficits can be financed by the use of that power, the effect is to make government spending free of the will of the citizens and their representatives. For the government is now in a position to finance its expenditures with funds it does not obtain from the people. Even to the extent the government's expenditures have the approval of the citizens and their representatives, the approval is gained fraudulently—it is gained under the delusion that because the expenditures can be financed by inflation they are not at the expense of the citizens.

Thus, von Mises was absolutely right to describe sound money as belonging in the same category as constitutions and bills of rights, as a safeguard against despotic governmental power, and to describe the gold standard as indispensable to the system of representative government.⁵³ When the gold standard is overthrown and the government gains the power to spend funds it does not have to obtain from the people, a veritable revolution occurs in the relationship between the government and the people.

When the government need not obtain its funds from the people, but can instead supply the people with funds, it can no longer easily be viewed as deriving its powers and rights from the people. The ability to inflate enables the government to throw off its status as the servant of the people, deriving its just powers from the consent of the governed, and to appear instead in the guise of the Provider and Father of the people, with the people deriving their existence, powers, and rights from the government. A greater revolution in the relationship between the people and the government cannot be imagined. Yet that is the revolution that the power to inflate has operated to effect in the circumstances and in the psychology of the American people of today. Hardly a year passes but they do not willingly sacrifice some further portion of their inheritance of freedom for some imagined largesse from the government.

In such a state of affairs not only does the government go on growing in size from year to year, both absolutely and relative to the rest of the economic system, but the only ultimate stopping point becomes a totalitarian socialist dictatorship, comparable to the dictatorships of Hitler and Stalin. The stage for such a dictatorship is set when the rising prices caused by inflation are suppressed by means of price and wage controls.

As demonstrated earlier in this book, the enactment of price and wage controls causes shortages and economic chaos, because it destroys the price system. This results in demands that the government seize control over the economic system by means of imposing a system of

rationing and the allocation of the factors of production. In this way, the government comes to decide what and how much of each item is to be produced, and by what methods, and who is to receive the product.⁵⁴ Finally, as we have seen, the effect of this de facto socialization is to add tyranny to the chaos. The government is not able to solve the problems created by the destruction of the price system, but acquires full power over the newspapers and publishing houses, and over everyone's employment and standard of living. Caught between the chaos it has created and the responsibility for everyone's material well-being that it has assumed, its continuance in power becomes possible only by ruthless suppression of critics and the creation of an environment of fear and hysteria. Thus, life comes to be characterized by all the hallmarks of a totalitarian state.⁵⁵

Between inflation and the enactment of price and wage controls usually lies a period of growing hostility to profit and interest incomes, which incomes inflation sharply increases in nominal terms and reduces or altogether eliminates in real terms. At the same time, inflation brings about a vast redistribution of wealth and income, in the process causing far greater impoverishment than enrichment. The victims, who are unaware of the facts, are led to believe that their suffering is the result of others' high profit and interest incomes and thus to demand price and wage controls both as a source of relief and as an act of justice.

The next two sections of this chapter will explain these consequences of inflation in close conjunction with its destruction of capital formation. Later sections will elaborate on the propositions that inflation sets the stage for traditional, deflationary depressions and that it causes rather than cures mass unemployment. They will also show why inflation possesses inherent tendencies toward acceleration, culminating in the destruction of the currency and, where the government blocks the development of an alternative currency, of money itself. The chapter will conclude with proposals for the reestablishment of a gold and silver monetary system, in the form of a 100-percent-gold-or-silver reserve against checking deposits and paper currency. It will show why such a system would be both inflation proof and deflation/depression proof, and would possess every other virtue that it is possible for a monetary system to possess.

4. Inflation as the Cause of a Redistribution of Wealth and Income

Inflation destroys the buying power of all assets and incomes which are contractually fixed in terms of a given number of dollars. In this category are savings deposits,

bonds, preferred stock, life insurance policies, and annuities and pensions, as well as employment contracts, sales and rental agreements, and even fire and theft insurance. In raising prices, inflation progressively diminishes the buying power that all these contracts represent.

At the same time, inflation operates to benefit those who are obligated to pay according to the terms of such contracts. It does so by sharply increasing the sums of money they can earn with the same effort and correspondingly reducing the difficulty they experience in obtaining the sums of money necessary to meet their obligations. Thus, businessmen and corporations with debts to pay, the common stockholders of such corporations, homeowners with mortgages, the owners of inventories of commodities of all kinds that are financed with borrowed money, wage earners with personal debts, and the businessmen and wage earners who hold contracts entitling them to buy or rent on fixed terms—all of these groups of people find that the sums of money they are able to obtain from their activities tend greatly to increase and thus to make it very much easier for them to pay the interest and principal on their debts.

Inflation is capable of utterly destroying the buying power of contractually fixed assets and incomes and correspondingly impoverishing those who depend on them, and equivalently relieving from all real obligation those who are obliged to pay according to the relevant contracts. It arbitrarily changes all contractual relations at least to some substantial extent and is capable of destroying them totally. Its potential for achieving a redistribution of real wealth and income is fully comparable to that of a political revolution on the scale of the French or Russian revolutions. It is significant that in both of these revolutions, a major inflation occurred, alongside of the open confiscations and redistributions.

The destruction of the buying power of assets and incomes that are contractually fixed, and the corresponding release from real obligation of those who are obliged to pay according to such contracts, is not the only means by which inflation redistributes wealth and income. As von Mises has shown, inflation never raises all prices and wage rates at the same time and to the same extent. It raises some prices and wage rates ahead of others, or more rapidly than others. Those whose selling prices rise relatively early or more rapidly, gain at the expense of those whose selling prices rise only later on or less rapidly. Inflation shifts the terms of trade in their favor. It makes their goods and services worth relatively more of other people's goods and services and other people's goods and services worth relatively less of their goods and services. The relatively higher selling prices of their goods and services means that their revenues and incomes have risen relative to the prices they must pay. At

the same time, those whose selling prices have not risen or which lag behind, find their revenues and incomes do not keep pace with the rise in prices, and they correspondingly lose.⁵⁶

In addition to the gains inflation provides to various private individuals and groups at the expense of other private individuals and groups, it should never be forgotten that inflation always represents an unearned gain to whoever is in a position to introduce the newly created money into the economic system through his spending—and a corresponding loss to the individuals who make up the rest of the economic system. This party—most often the government or those to whom the government gives the money, but frequently also businessmen with fiduciary media to spend—is able to obtain the goods and services of others merely by virtue of the manufacture of little pieces of paper, or, indeed, merely by virtue of bookkeeping entries. Such a situation represents the receipt of something for nothing, and must be accompanied by an equivalent receipt, somewhere else in the economic system, of nothing for something. Somewhere else in the economic system, others must to the same extent consume less, produce more without consuming more, or suffer a loss in their accumulated capitals (or undergo some combination of these three), in order to compensate for the unearned gains of the spenders of the new money.⁵⁷

Ironically, the groups which tend to lose the most as the result of inflation are the relatively poor and helpless—i.e., the very people that the welfare state claims it wishes to help. It is widows and orphans and the elderly, who depend most on the buying power of savings deposits, life insurance policies, pensions, and annuities. Similarly, institutions such as nonprofit hospitals and nonprofit colleges and universities, are also among those most dependent on the buying power of bonds and other contractually fixed assets, which, for the sake of safety of principal, must form a substantial portion of their endowments. It follows that it is inherently dishonest for the welfare state to claim that it seeks to aid these groups and institutions when its inescapable dependence on inflation makes precisely them its worst victims. The welfare state is both an exercise in futility and a fraud. By its nature, it harms those it claims to help. Its advocates have no legitimate reason not to know this.

Eventually, people come to recognize the destructive effects of inflation in redistributing wealth and income, and take steps to protect themselves from them. Thus, interest rates rise in anticipation of the rise in prices to come. The terms of employment, sales, and rental contracts are increased. Price indexing is introduced into various contracts. But these remedies are at best only

partially effective, and create additional problems, namely, unemployment and/or the acceleration of inflation, as will be shown.⁵⁸

5. Inflation and the Destruction of Capital

Inflation undermines capital formation in five major ways, which can be described under the following heads: reversal of safety, tax effects, prosperity delusion and overconsumption, malinvestment, and the withdrawal-of-wealth effect. Each of these ways will be considered in turn.

Reversal of Safety

The traditionally safest investments are high-grade corporate bonds, savings deposits, life insurance policies, and government securities. Inflation turns the safety of these investments upside down. It is capable of rendering them the least safe forms of investment. It introduces the risk that the buying power of the proceeds of these investments will be little or nothing. It makes all long-term contracts denominated in a fixed sum of money utterly meaningless, because it places the value of money totally at the mercy of government officials and pressure groups. It is as though one contracted for the delivery of so many tons of coal or board feet of lumber, without the words "ton" or "feet" having any objective meaning and thus subject to the whims of whoever might later care to assert an interest. This is the position of everyone who is contractually entitled to receive fiat money. The only thing he can be certain of is that when he receives the money due him, it will be worth substantially less than it is presently worth.

Yet contractually fixed investments are economically necessary. They are the appropriate investment vehicle for individuals not able or willing to bear substantial risk or to search out and follow more complicated types of investments, such as common stocks. As a result, the destruction of this type of investment deprives a large group of people of the possibility of benefitting from investment. To the extent that the prospect of earning a rate of return on investment constitutes a motive to save, such individuals are deprived of the motive to save. At the same time, they are largely deprived of the means of saving. They are deprived of the means of saving insofar as they are deprived of income on their investments, which income is normally a major source of further saving.

And to the extent they do continue to save, their saving increasingly tends to take an unproductive form. A leading example of the unproductive use of savings that results from inflation is the hoarding of precious metals, whose prospective rise in price in the course of inflation offers people the ability to preserve the purchasing power

of their savings. Unfortunately, such hoarding does not contribute to investment.

This is certainly not to criticize the hoarding of precious metals. If the government destroys the traditionally safe investments, such hoarding is the best substitute most individuals have. And it is to everyone's interest that individuals continue to have the motivation to save, even though their saving takes the form of such hoarding. This is because if the government prevented them from doing even this, and thus totally destroyed the benefit they could derive from saving, it would deprive people of much of their motivation to work. In the absence of being able to save, people would lose the motivation to perform present labor for the sake of providing for their future wants; their only motivation to work would be to satisfy their present wants, which often would not be important enough to justify their labor. Furthermore, it should be realized that the desire to own precious metals need not take the form of hoarding. If the government permitted and enforced contracts calling for payment in precious metals, and if the tax authorities did not tax the rise in their price expressed in terms of paper money, then the precious metals could themselves be lent and so contribute to investment. But this would be tantamount to their remonetization and would mean the transformation of the whole monetary system.

In any case, it is clear that the effect of inflation is to reduce both the motivation to save and the motivation to invest productively such savings as do continue to be made. This obviously impairs the formation of capital, and not only of new capital but also the replacement of existing capital, since people are motivated to consume what they have saved in the past, or to convert it into unproductive hoards. In both ways, the effect is to raise the rate of net consumption.⁵⁹

The prospective purchasing power of fiat money rests on a foundation that is far more precarious than the general public realizes. In the first instance, it depends on the rate of increase in the quantity of the money over the period of time that the fixed-sum-of-money investments in question are outstanding. Since the rate of increase in the quantity of fiat money is totally at the discretion of government officials, the more fundamental determinants of the rate at which its purchasing power declines are such factors as the government officials' knowledge of economics, their sense of moral responsibility, and even their method of thinking. This constitutes a truly alarming situation.

The majority of government officials today, and the majority of academic economists, whose ranks supply the advisers of the government officials, do not even firmly acknowledge the truth of the quantity theory of

money. These officials and alleged economists continue to attempt to blame rising prices on almost everything but the increase in the quantity of money. They talk of the greed of businessmen and labor unions, of the price of imported oil, of inflation psychology, of credit cards, and the greed of consumers. In a word, they are wedded to all the fallacies I refuted in the first part of this chapter.

Thus, those who have charge of the increase in the quantity of money, who have the power to increase it as much as they wish, either do not know or will not admit the consequences of increasing it. This is a state of affairs comparable to being in the power of someone who holds a gun but does not know or will not admit the lethal power of his weapon.

Among the government officials and their advisers who do admit the truth of the quantity theory of money, there are many—perhaps a further majority—who believe that what is true in theory is not necessarily true in practice or who, for other reasons, are prepared to act without integrity. In such cases, even a knowledge of the quantity theory of money does not serve as a reliable restraint on the increase in the quantity of money. Closely related to this is the fact that government officials labor under a variety of extremely powerful temptations to use their power to expand the quantity of money. The use of this power is the supreme vote-buying technique: it caters to all the fallacies held by the public about “free” benefits, from free education and medical care to “easy money,” and about what must be done to prevent or combat unemployment.⁶⁰

In view of the enormous ignorance concerning the nature of inflation and its effects, the widespread lack of integrity on the part of today’s public officials (and professional intellectuals), and the extremely powerful political motives in support of inflation, there is little hope that, given the power to create money, the government will not use it far beyond the point of prudence. Moreover, because of the inherent accelerative tendencies of inflation, yet to be explained, the rate at which the government is motivated to increase the quantity of money is steadily increased as inflation becomes more rapid.⁶¹

Thus, investments denominated in fixed sums of money are in fact transformed from the safest into the most speculative and risky from the perspective of the purchasing power they will provide. This is a situation which must increasingly undermine saving and investment by the broad classes of the public that depend on such investments.

Tax Effects

As was shown earlier, inflation simultaneously increases nominal profit incomes, which are subject to tax,

and the replacement prices of capital assets. It creates profit incomes most or all of which are required merely for the replacement of assets at the higher prices it causes, but which cannot be applied to replacement because they are taxed away as though they were genuine income.

Previous discussion of this fact used an example in terms of inventories. The example showed that despite earning a sharply higher nominal rate of profit as the result of inflation, the typical merchant is placed in a position in which, after making the necessary replacement allowance for the assets needed to continue his existing operations, his ability either personally to consume or to save and expand his business, is actually radically reduced.⁶² The following example illustrates the same principle in application to fixed assets, such as plant and equipment and buildings.

As can be seen in Table 19–1, I assume that a machine (or any other form of fixed capital) initially costs \$1 million and lasts 10 years. The annual depreciation on this machine, using the common, straight-line method, is thus \$100,000. I assume that initially, without inflation, the machine is used to produce a quantity of goods each year that sells for \$1 million. I further assume that operating costs—the cost of the labor, fuel, and materials required to produce these goods—are \$850,000 per year. Thus, the firm’s annual gross profit (its profit before deduction of depreciation cost) is \$150,000 per year.

After deducting depreciation, the firm’s net profit is \$50,000 per year. If the firm must pay a 50 percent income tax on its profit, its after-tax profit is \$25,000 per year. If, out of that sum, it pays a dividend of \$10,000, then it has \$15,000 left with which to expand its operations. This is the situation shown in the column labeled “Without Inflation.”

Now let us imagine that between the time the firm buys its machine and the time at which it will have to replace it, an increase in the quantity of money and volume of spending occurs which doubles the firm’s sales revenues and operating costs, and, of course, the replacement price of a new machine. Under these conditions, the firm will have an annual gross profit of \$300,000 (\$2 million in sales revenues minus \$1.7 million in operating costs). However, because the purchase price of its machine is not affected retroactively, its deduction for depreciation on its existing machine remains at only \$100,000. Its net profit before taxes is therefore raised to \$200,000 per year—quadruple its previous net profit of \$50,000 per year before taxes. If the firm still pays the same, 50 percent tax rate, its net profit after taxes is \$100,000 per year, which is also quadruple what it was initially.

The apparent quadrupling of profits seems wonderful indeed, until we consider the need to replace the machine

Table 19-1
Effect of Inflation on the Nominal Rate of Profit and the Taxation of Profits

	Without Inflation	With Inflation
A machine (or any other form of fixed capital) costs \$1,000,000 and lasts 10 years.		
Sales Revenues	\$1,000,000	\$2,000,000
Operating Costs	<u>850,000</u>	<u>1,700,000</u>
Gross Profit	150,000	300,000
Depreciation	<u>100,000</u>	<u>100,000</u>
Net Profit Before Tax	50,000	200,000
Tax (50%)	<u>25,000</u>	<u>100,000</u>
Net Profit After Tax	25,000	100,000
Necessary Reserve for Replacement at Higher Prices	NONE	100,000
Available for Consumption or Expansion	25,000	NONE
Dividend	10,000	10,000
Reinvested Earnings	15,000	(10,000)

at a price of \$2 million instead of only \$1 million. When we do this, the seemingly rosy picture of enormous profits turns into something very different. For then it becomes clear that if our firm gives to its stockholders *any dividend at all*, it must impair its ability to continue doing business on the same scale, because *the whole of the firm's seemingly larger profit each year is required merely to enable it to replace its machine at the now higher replacement cost*. That is, in order to accumulate the replacement sum of \$2 million, our firm needs to set aside \$200,000 for each of 10 years. This sum, however, is equal to its annual depreciation of \$100,000 plus the whole of its after-tax "profit" of \$100,000. In the table, this is shown by means of the row labeled "Necessary Reserve for Replacement at Higher Prices," the amount of which is "NONE" in the column labeled "Without Inflation," and \$100,000 in the column labeled "With Inflation." The table shows that as a result of the need to deduct this reserve under inflation, the funds available for consumption or expansion from the nominal profit of \$100,000 turn out to be "NONE," while the much smaller

nominal profit of \$25,000 earned without inflation is sufficient to make possible consumption or expansion to its full extent. Thus, under inflation, if the firm pays even the same dividend it previously paid—\$10,000 per year—let alone the substantially larger dividend its stockholders are almost certain to clamor for in view of its sharply increased "profits," it cannot generate the funds it requires for replacement. As is shown in the table, its reinvested earnings must fall by an amount equivalent to that \$10,000. (The reduction of \$10,000 in reinvested earnings should be understood as being in real terms, not nominal terms. In nominal terms, if the firm pays a \$10,000 dividend, its nominal capital will rise by \$90,000. Its problem is that to maintain its physical capital intact, it needs to increase its nominal capital by \$100,000, not just \$90,000.)

Once again, therefore, we see that to the same extent that inflation provides additional profits, it also requires that those profits be devoted to the replacement of assets at higher prices. Yet this fact is largely ignored in the collection of taxes. What is involved in this case, as well

as in the earlier, inventory case, is that as a result of inflation, *the firm is taxed not merely on its income, but on funds required for the replacement of its capital as well.* If its income properly begins only after full and complete allowance for replacement has been made, then its taxable income should not be viewed as \$200,000, but only \$100,000, since \$100,000 of its apparent profit of \$200,000 is actually required to be set aside for replacement. In taxing the firm on \$200,000 rather than just \$100,000, therefore, the government taxes the firm on the replacement of its capital as well as on its income. To say the same thing in somewhat different words, the firm should be able to deduct the item "Necessary Reserve for Replacement of Assets at Higher Prices" from its pretax income, and thus pay taxes only on the amount remaining thereafter. Instead, of course, the firm is taxed as though the funds required for the replacement of assets at higher prices were income.

In creating profits which are required for the replacement of assets at higher prices and which nevertheless are subject to taxation, inflation operates as the equivalent of a rise in income tax rates on real profits. In the above illustration, its operation is equivalent to raising the rate of income tax on real profits from 50 percent to 100 percent, because it doubles the nominal profit subject to tax, while the real profit earned remains unchanged.

The result of such increases in effective tax rates is that business finds itself with less and less ability to expand or even maintain its operations intact as inflation grows worse. Vast stretches of the Northeast and Midwest, with their abandoned factories and decaying housing, are a testimonial to this destructive consequence of inflation, as is the inability of broad segments of surviving American industry to modernize to keep pace with foreign competitors. Nevertheless, despite the visible decline of the American economic system in recent decades, inflation and the nominal profits it creates make it possible for virtual hoards of the ignorant, the envious, and the downright malicious to denounce profits as excessive and to claim that they are not taxed sufficiently!

Essentially the same principles as apply to businessmen and corporations apply to lenders, who appear to be earning unprecedentedly high rates of interest and yet are being impoverished at the same time. The position of the typical creditor in a period of inflation is that after taxes are deducted from his receipt of interest, and allowance is made for the rise in prices, his real wealth—the buying power of his principal—shrinks. Anything he consumes out of his seeming income is actually at the expense of his capital.

Imagine, for example, a lender who instead of earning

a 4 percent rate of interest earns a 14 percent rate of interest. However, when he earns the 14 percent rate of interest, prices are rising by 10 percent a year. In terms of buying power, this lender is no better off than he was before, despite the much higher rate of interest that he earns. Indeed, he must be substantially worse off, because out of his seeming 14 percent rate of return, he will have to pay a substantial portion in taxes. If we assume that he pays half in taxes, he is left with only a 7 percent rate of return in the face of a 10 percent rise in prices. And to whatever extent he consumes any portion of his "rate of return," his situation is made so much the worse in terms of the preservation of the buying power of his capital.

Once more, the situation is that inflation makes the income tax operate as a tax on capital. The lender's taxable income should begin only after allowance has been made for the maintenance of the purchasing power of his principal—viz., the portion of his interest equal to the rise in prices should not to be subject to taxation. Yet he is taxed on this portion of his income, even though it represents merely the maintenance of the purchasing power of his principal.

It should be noted that inflation produces essentially the same effect in connection with capital gains taxation, despite the fact that the rate of tax applying to capital gains may be less than the rate of income tax. For it creates capital gains all of which are required for the replacement purchase of similar capital assets at higher prices, but which are nevertheless taxed away as though they were genuine gains.

Inflation plays a major role in the decline of the highways and other so-called infrastructure of a country, which is typically maintained by the government. Government officials, usually shortsighted to begin with, rarely allow for the effects of inflation on the replacement costs of the assets they manage. Thus, as inflation pours new and additional revenues into their hands, they proceed as though the revenues were available for the expansion of government activities, and neglect the need to devote an adequate portion of them to replacement and maintenance at progressively rising prices. The result is decaying water and sewage systems, subway and rail lines, and bridges and tunnels, as well as decaying roads and highways.

The Prosperity Delusion and Overconsumption

The overstatement of income that results from inflation is the cause not only of the taxation of replacement funds, but also of excessive private consumption which comes at the expense of capital formation and which would be a serious problem even in the absence of

taxation. This overstatement represents what is often described as the prosperity delusion of inflation—the creation of an appearance of prosperity based on the mere increase in paper profits.

Our example of the machine clearly shows the nature of the problem. The stockholders and management of the company that owns that machine will believe that their firm is in a position to afford substantially increased dividends on the basis of its sharply increased profits. Years may go by before they become aware of the deficiency of replacement funds, and even then they may not realize that they had no genuine profit and should not have taken the dividends they did.

It must be stressed that overconsumption exists even if the owners of a business base their consumption entirely on their perception of their accumulated capital rather than their income, and at first save, or allow their firm to save, almost all of the additional profit that inflation generates for them. In this case, the effect of inflation will be an overstatement of their capital equal to the progressive understatement of accumulated depreciation, and thus an overconsumption corresponding to that overstatement of capital.

The problem of overconsumption is greatly compounded to the extent that there are stockholders and other business owners who are ready to use the occasion of higher profits as the basis for going on a “binge” of any sort. Inflation relaxes the normal competitive pressures of the market that constantly tend to minimize the economic influence of such people through the regular gravitation of capital and profit to those individuals who consume the least and save the most.⁶³ The existence of inflation represents giving people with the binge mentality a continual new lease on life. It continually provides them with the profit incomes they can use to indulge themselves.

The capital gains that inflation systematically creates in the purchase and sale of land and buildings of all kinds, and in commodity futures and common stocks, are also the source of substantial increases in consumption, as the beneficiaries of the process enjoy the apparent experience of growing richer. Inflation leads practically everyone to overconsume on the basis of the delusion of a prosperity that does not exist. Everyone who sells an asset at a higher price, such as a house or common stocks, almost certainly thinks he has gained something and can now afford to consume something he previously could not have afforded to consume. Yet, in reality, the same process that has produced his monetary gain has raised the prices of replacement assets and other goods on average to the same extent. If he consumes any part of that gain, he cannot replace the assets he has sold with comparable assets, nor maintain the buying power of his

nominal wealth or capital. There is no more actual foundation for additional consumption than the fact that some extra pieces of paper have been printed in a certain way or that some bookkeeping entries have been made.⁶⁴

In some cases, indeed, individuals actually do grow richer as the result of inflation. For example, an individual who buys a \$100,000 house or piece of land with a \$20,000 down payment and a mortgage of \$80,000, and who sells it a few years later for \$200,000, makes a profit of 500 percent, since he pockets the full appreciation of the asset. Even if all other prices double along with the price of his asset, he comes out far ahead, because of the leverage of his investment.

Although the prosperity of these individuals is genuine, an overconsumption exists nonetheless, in that their gain merely represents the equivalent or even greater loss of others. For example, the individuals whose savings provided our homeowner’s mortgage have a loss at least as great as his gain. This is because when the price of the house and all other prices on average double, these individuals lose half the buying power of the \$80,000 they lent him. By the same token, the \$120,000 equity of the homeowner represents \$60,000 of buying power in terms of the original level of prices. In other words, what inflation does is equivalent to taking \$40,000 from the savers who financed the mortgage, and give it to the homeowner. It is a mere redistribution of the same total sum of existing wealth, with the homeowner-gainer then consuming a substantial portion of his gain, while no equivalent reduction in consumption takes place on the part of the saver-losers.⁶⁵

The additional consumption of the gainers from inflation is almost certain to be greater—in real terms—than the diminished consumption of the losers, because the gains go largely to people who have no special penchant for saving and providing for the future, and come at the expense of those who do. The gains from inflation come as a windfall, which the beneficiaries have not had to earn and frequently do not count very confidently on being able to keep. As a result, much of the gains are likely to be squandered. In redistributing wealth, inflation has the effect of converting previously accumulated savings and capital into an unearned current income largely of people who are bent on consumption rather than saving and provision for the future. In this way as well as others, inflation operates to raise the rate of net consumption.

In the case of a lender, it is perhaps misleading to speak of “a prosperity delusion” created by inflation, because the lender almost certainly realizes that he is falling behind. In his case, inflation serves to conceal the extent of impoverishment. It creates the illusion that in spite of his impoverishment, he still has an income, out

of which he can afford to consume, when in actuality he does not. He would consume far less if, as in one of our previous examples, instead of having an “income” of 7 percent while prices rise by 10 percent, he had a monetary loss of 3 percent with no rise in prices, because then the true state of affairs would be real to him. He would directly perceive a loss instead of an “income” that somehow happened to be accompanied by a rise in prices of a greater magnitude but which he did not perceive as intrinsically connected.

Wage earners, too, are led to overconsume on the basis of the delusion of having higher real incomes than they actually do. In a period of inflation, with prices steadily rising, everyone has an exaggerated idea of the purchasing power of money, based on his past experience of prices, which, necessarily, is now outmoded. For example, his notion of the purchasing power of money rests in part on his estimate of the price of a new car or washing machine. But that estimate is based on his last experience of the prices of such goods, which may have occurred several months or even several years in the past, at which time the prices were undoubtedly lower than they are today. Thus, people consume in the mistaken belief that their incomes will enable them to afford to buy more than is actually possible at the now higher level of prices. In other words, they consume in the belief that they are richer than they really are, and thus on a scale that they cannot afford in their actual circumstances.

Malinvestment

In Chapter 12, I explained how in raising the rate of profit, inflation also raises the rate of interest. However, it must be kept in mind that the rise in the rate of interest tends to lag behind the rise in the rate of profit insofar as inflation enters the economic system in the form of credit expansion—i.e., the granting of new and additional loans out of the newly created money. The presence of these additional funds in the loan market prevents the rate of interest from rising as high as it would on the basis of the rise in the rate of profit alone. In the initial phase of credit expansion, the rate of interest actually falls.⁶⁶

Now the artificial rise in the rate of profit, combined with the lag in the rate of interest, leads to the wasteful investment—the *malinvestment*—of the reduced capital that inflation leaves still available. Projects without genuine economic merit are made to appear profitable merely by virtue of the existence of inflation, and a relatively low rate of interest ensures that capital will be diverted to them as a result. The following hypothetical examples illustrate the process.

Thus, imagine that inflation is currently raising prices on the order of 15 percent a year. Imagine further that because much of the inflation enters the economic sys-

tem in the form of loanable funds, interest rates have thus far risen only to 10 percent. Now imagine a specific commodity, say, copper, whose price rises as fast as the average of prices. If the storage costs of copper are less than 5 percent a year, inflation in the form of credit expansion makes it profitable to stockpile copper—not because there is any real need to stockpile copper, but just because inflation in the form of credit expansion itself makes it profitable. (Without inflation in the form of credit expansion, the combination of storage and interest costs would make it highly unprofitable to stockpile copper, in the absence of some special, important need for copper that could not be met by future production.) Thus, copper is withdrawn from use, to be stockpiled, and labor and capital are wasted in the production of the stockpile.

This example shows how, even apart from the problems of taxation and overconsumption, inflation in the form of credit expansion makes a direct *loss* of wealth in an investment appear profitable all the same. For consider. Even if the price of copper rises by the same percentage as the rise in prices in general, once the storage costs are deducted from that rise, the investment in copper must entail a loss overall. If, for example, the storage costs are 3 percent a year, then the gain in money by investing in a stockpile of copper whose price rises by 15 percent, is only 12 percent. At the same time, prices in general rise on average by 15 percent. This represents a 3 percent loss in the actual buying power of the investment. But if the money for the investment can be obtained from lenders at a rate of interest of 10 percent, then the lenders suffer a loss of 5 percent in the buying power of their capital, while the borrowers, after deducting storage costs, come out with a gain equal to 2 percent of the capital invested. (The borrowers’ rate of return on their own capital depends on how highly leveraged they are. If they can borrow the entire amount, their rate of return is infinite. If they can borrow nine-tenths of the capital, their rate of return is 20 percent—viz., 2 percent on the investment as a whole, divided by the 10 percent of the total investment that they themselves put up.) In effect, the loss of the lenders covers both the loss on the investment as a whole and, at the same time, provides the source of gain for the borrowers. In other words, inflation creates a situation in which one class of investors feeds off the capital of another, while the total capital of both classes of investors combined shrinks. The rest of the economy, of course, is deprived of the benefit of capital, both the benefit of the capital that ceases to exist, because it is lost, and, to a greater or lesser extent, the benefit of the capital that is malinvested.

Similar malinvestments as occur in the stockpiling of all kinds of materials, occur in the construction of hous-

ing and plant and equipment. For example, inflation makes the price of houses rise from year to year. If the rate at which the price of houses rises is higher than the rate at which mortgage money can be borrowed—because mortgage rates are held down by the fact that much of the new money enters the economic system in the form of loans—then the purchase of houses, a *consumers' good*, takes on the appearance of an investment. As a result, capital is diverted into the purchase of houses, and further capital is diverted into their construction. After purchase, the houses depreciate and suffer a corresponding loss in real value; but the losses of lenders are great enough to finance both the overall loss on the investment as a whole and a gain to the borrowers.

To use a modification of our previous example concerning housing, let us assume that while prices in general triple, the price of a given house, which grows older every year and physically depreciates, merely doubles. The overall investment in the house thus loses one-third its original buying power. Yet, if the home buyer has had to put only 20 percent of the price down, he increases his equity by a factor of 6, inasmuch as the 100 percent rise in the price of the house accrues all to him. And thus he comes out doubling his real wealth—viz., he has 6 times the equity in the face of a tripled price level. Both his gain and the overall loss on the purchase of the house are financed by the lenders, who lose two-thirds of the purchasing power of the money they lent by virtue of the tripling of prices. Using a \$100,000 house for illustration, the home buyer's equity goes from \$20,000 to \$120,000, while the mortgage lender's principal does not rise above its initial \$80,000. With a tripling of prices, the house, at \$200,000, is worth what \$66,667 was worth at the time of its purchase. The homeowner's \$120,000 equity is worth what \$40,000 was worth at the time the house was purchased. The lender's \$80,000 is worth only what \$26,667 was worth at the time of purchase. The loss to the lender, in terms of dollars of the original buying power, is \$80,000 minus \$26,667, that is, \$53,333. This loss finances the loss of \$33,333 on the investment as a whole in terms of dollars of the original buying power, plus the gain of the homeowner borrower of \$20,000. And so it is in all cases of this kind.

The worse inflation in the form of credit expansion becomes, the worse becomes the problem of malinvestment. With a high enough rate of inflation, it may even pay to "invest" in such things as passenger automobiles, because their price as one-year-old used cars may exceed their price the year before as new cars by more than enough to cover the interest costs involved.

In order for malinvestment to occur, however, it is not necessary that inflation be strong enough to make prices actually rise or that capital be diverted into investments

in which the overall rate of return is negative. As von Mises has shown, credit expansion, and the artificial reduction in the rate of interest it causes (whether that reduction is absolute or only relative to the rate of profit), creates the appearance of a more abundant supply of capital than in fact exists. That is, the mere manufacture and lending of banknotes or deposit entries does not create any actual additional capital, but only the appearance of additional capital. On the basis of this appearance, businessmen are led to undertake projects for whose execution the actual supply of capital is inadequate. Such use of capital, for purposes inappropriate to the actual supply of capital, constitutes malinvestment. Even if the use of the capital does not entail an outright loss in real terms, it still represents a diversion of capital from more important to less important uses. It is still a wasteful, inefficient use of capital, hence, malinvestment.⁶⁷

The effect of all malinvestment of capital is a reduced overall ability to produce, since the capital required for production is used inefficiently. This impairment of the ability to produce causes a reduced ability to produce *capital goods* no less than consumers' goods. And this, in turn, represents a *further* source of diminution in the supply of capital goods in the future. Anything which, like malinvestment, impairs the ability to produce impairs the future supply of capital goods, because, as we have seen, the source of capital goods is production itself.⁶⁸

The phenomenon of malinvestment provides an important illustration of the fact that inflation does not raise all prices at the same time and to the same extent. So long as credit expansion is capable of inducing malinvestment, it tends to raise the prices of such things as storable commodities and houses relative to most other prices, by virtue of creating an artificial additional demand for them based on the desire to take advantage of the special profit that credit expansion creates in those lines. Later, when inflation in the form of credit expansion stops, slows, or simply fails to accelerate sufficiently—with the result that interest rates rise to the point of eliminating the profitability of the malinvestments—these prices fall relative to most other prices. For then the ground is cut from under the additional demand for them. This knowledge sheds important light on major movements in the commodity and real estate markets.

The Withdrawal-of-Wealth Effect

As we have seen, the very act of spending newly created fiat money or fiduciary media must inflict losses somewhere in the economic system equal to the unearned gains of the spenders. Such spending represents an uncompensated withdrawal of wealth from producers in

that the spenders draw wealth out of the system without putting wealth in. The individual businesses that receive the new and additional money may not be aware of this fact, because they can reexchange the money for the goods and service of others. But the loss must fall somewhere in the economic system.⁶⁹

The withdrawal-of-wealth effect represents a diversion of capital to consumption insofar as the spenders of the new and additional money are consumers and probable malinvestment insofar as they are business firms. The latter conclusion is implied in the fact that the firms which depend on the creation of new and additional money have proved unable to compete for capital on the regular loan market and require the subsidy that credit expansion represents.

It is almost impossible that the withdrawal-of-wealth effect could make possible an increase in capital goods at the expense of consumption, as some advocates of credit expansion have claimed in putting forward the doctrine of "forced saving." This is because the proceeds of credit expansion are themselves largely used to finance the purchase of consumers' goods; and of the credit expansion that is used for business purposes, a substantial portion goes for the payment of wages, which, directly or indirectly, are all or almost all consumed. Thus, it is highly unlikely that credit expansion and the withdrawal-of-wealth effect could operate as a tax on consumption in favor of capital accumulation. And when placed in the context of all the other ways that inflation and credit expansion undermine capital formation, the notion that credit expansion promotes capital formation must be judged patently absurd.⁷⁰ As we have seen, the effect of inflation and credit expansion is to increase consumption expenditure relative to productive expenditure and to increase the rate of net consumption.

6. Consequences of the Destruction of Capital

Reduction of the Real Rate of Return

All five of the effects described have been shown to operate against capital accumulation. The reversal-of-safety, tax, malinvestment, and withdrawal-of-wealth effects also operate to *reduce the real rate of return on capital*. The reversal-of-safety effect threatens all who invest in the traditional ways with the loss of their capital and thus with the receipt of no rate of return at all, or, indeed, a negative one. The tax effect represents the taxing away of the real rate of return. The malinvestment effect represents the investment of capital in ways that are less efficient and actually loss making. The withdrawal-of-wealth effect represents the withdrawal of wealth that constitutes part or all of firms' real rate of return on capital.

It must be stressed that these reductions in the real rate of return occur in conjunction with *less* capital formation, not an abundance of capital, as the advocates of credit expansion believe. The process can be compared to the effect on the income statement of a firm, of a fire in its warehouse, or some similar calamity. It has less wealth and when it enters the reduction in its wealth on its balance sheet, it must make an equivalent charge against its income, in its income statement. Of course, none of this should really be surprising in view of the pervasive, direct and intimate relationship that we have established between aggregate profits and net investment.⁷¹

The Gains of Debtors Less Than the Losses of Creditors

A further consequence of the undermining of capital formation, and the accompanying reduction in the real rate of return on capital, is that the gains from inflation enjoyed by debtors are less than the losses suffered by creditors. The reduction in the overall real rate of return on capital investment as such means that there is less gain for all investors combined to share. Thus, any increase in the gains enjoyed by stockholders and other classes of business debtors must be accompanied by losses on the part of bondholders and other classes of creditors that are even greater, for the latter must provide not only the gains of the stockholders and other business debtors, but also make good the reduction in the overall real rate of return on capital as such that takes place.

The phenomenon of the gain of debtors being less than the loss of creditors is obvious in the case of malinvestments that are extreme enough actually to be loss making on an overall basis, yet turn out to be of benefit to borrowers. It is particularly glaring in cases in which *consumer* borrowers, such as homeowners, the inherent nature of whose activity is to use up wealth, are able to increase their wealth, by virtue of having borrowed at a rate of interest that is sufficiently below the rate at which prices rise. But it is present to some substantial degree throughout the economic system, whenever credit expansion takes place. And, of course, debtors, no less than creditors, bear the full brunt of the stepped-up taxation of profits that inflation and credit expansion engender, even to the point of being deprived of any real rate of return whatever. Both categories also suffer from the inducements to overconsumption that inflation and credit expansion create.

The Impoverishment of Wage Earners

Because of inflation and the rise in consumption and accompanying undermining of saving and productive expenditure that it causes, both the relative production of capital goods and the degree of capital intensiveness in

the economic system are less. In addition, the efficiency with which existing capital goods are employed is less. All of these factors, of course, operate to reduce the supply of capital goods available for use in production. Since the productivity of labor vitally depends on the supply of capital goods, inflation operates to reduce the productivity of labor. This means, of course, that it operates to reduce real wage rates.⁷²

Inflation operates to reduce real wages also by virtue of the fact that real wages depend on the demand for labor relative to the demand for consumers' goods.⁷³ And the demand for labor, of course, depends on saving and productive expenditure.⁷⁴ In raising the rate of net consumption and thereby retarding the growth in saving and productive expenditure relative to the growth in the demand for consumers' goods, inflation retards the growth in the demand for labor relative to the growth in the demand for consumers' goods, and in this way too operates to reduce real wage rates.

Thus, by virtue of its effect both on the productivity of labor and on the so-called distribution factor—viz., the demand for labor relative to the demand for consumers' goods—inflation tends to make prices rise at a more rapid rate than wage rates and thus to bring about a corresponding reduction in real wage rates.

It is important to realize that insofar as the government and labor unions attempt to resist the tendency toward the fall in real wages, by forcing wage rates to increase as fast as prices, the effect of their action is to cause unemployment. Insofar as prices rise because of a decline in the productivity of labor or because of a growth in the demand for consumers' goods in excess of the growth in the demand for labor, any attempt to make wage rates rise equivalently is an attempt to make them rise without benefit of a rise in the demand for labor. This is an important, though not the most important, way in which inflation actually causes unemployment rather than prevents or remedies it.

The Stock Market and Inflationary Depression

The fact that inflation undermines capital formation has important implications for the performance of the stock market. In its initial phase or when it undergoes a sufficient and relatively unanticipated acceleration, inflation in the form of credit expansion can create a stock-market boom. However, its longer-run effects are very different. The demand for common stocks depends on the availability of savings. In causing savings to fail to keep pace with the growth in the demand for consumers' goods, inflation tends to prevent stock prices, as well as wage rates, from keeping pace with the rise in the prices of consumers' goods.

The same consequence results from the fact that infla-

tion also leads to funds being more urgently required internally by firms—to compensate for all the ways in which it causes replacement funds to become inadequate. At some point in an inflation, business firms that are normally suppliers of funds to the credit markets—in the form of time deposits, the purchase of commercial paper, the extension of receivables credit, and the like—are forced to retrench and, indeed, even to become demanders of loanable funds, in order to meet the needs of their own, internal operations. The effect of this is to reduce the availability of funds with which stocks can be purchased, and thus to cause stock prices to fall, or at least to lag all the more behind the prices of consumers' goods.

When this situation exists in a pronounced form, it constitutes what has come to be called an “inflationary depression.” This is a state of affairs characterized by a still rapidly expanding quantity of money and rising prices and, at the same time, by an acute scarcity of capital funds. The scarcity of capital funds is manifested not only in badly lagging, or actually declining, securities markets but also in a so-called credit crunch, i.e., a situation in which loanable funds become difficult or impossible to obtain. The result is widespread insolvencies and bankruptcies.

7. Inflation as the Cause of Depressions and Deflation

Inflation, especially in the form of credit expansion, sets the stage for financial contractions and deflations—i.e., for depressions. It does so in several, related ways.

It undermines the perceived need and the desire to own money balances. As a result, it causes a more rapid spending of money—a rise in the so-called velocity of circulation of money. An integral part of this process, of course, is a growing state of financial illiquidity—a declining ratio of cash holdings to current liabilities.

These results occur in large part because credit expansion creates the prospect of being able to obtain the money needed to make purchases and pay bills, easily and profitably through borrowing. The prospect of loans manufactured out of thin air by the banking system is substituted for the holding of actual money, with the result that businesses are led to draw down their cash reserves in making loans and investments they otherwise would not have made.⁷⁵ For they expect that when they need money they can readily obtain it from their banks. The fact that credit expansion, and the creation of money in any other form, causes the demand for goods and services to grow makes the holding of additional inventories also appear as a welcome substitute for the holding of money as the means of assuring the ability to make purchases and pay bills in the future, since in a rising market the inventories can be liquidated all the more

easily and profitably.

These mechanisms are reinforced by the fact that after a while, inflation—even in the form of credit expansion—raises interest rates. This, of course, makes it worthwhile for people to lend out short-term sums of money that it otherwise would not have been worthwhile to lend out and would thus have remained in cash holdings. Finally, as inflation proceeds to the point of raising prices, people sooner or later become accustomed to the rise in prices and come to expect them to go on rising. When this happens, they start buying sooner, before prices rise further.

In all of these ways, inflation of the money supply brings about an even greater increase—a superinflation, as it were—in the volume of spending in the economic system, and a corresponding diminution in the size of cash holdings relative to spending and to current liabilities. Spending rises not only because there is more money, but also because the increase in the quantity of money reduces the perceived need and hence the desire to own money.⁷⁶

The other side of spending, of course, is people's revenues and incomes, since one man's spending is another man's receipts. Obviously, in superinflating the volume of spending in the economy, inflation also superinflates people's revenues and incomes.

Inflation also does something else. It encourages people to pile up a mass of debt that they can pay only so long as their revenues and incomes hold up—indeed, only so long as their revenues and incomes go on increasing. Inflation in the form of credit expansion encourages borrowing by holding down the rate of interest in relation to the rate of profit. It makes borrowing exceptionally profitable; and the more so, the more leverage the borrowing provides. Another important way that inflation encourages debt is simply by leading people to borrow in anticipation of rising prices. Housing purchases have been a prime example of this effect of inflation. People go heavily into debt to buy houses at already inflated prices, because they expect housing prices to go on rising. The same thing happens with business spending for plant and equipment and inventories.

Thus, inflation does two critical things. It superinflates people's revenues and incomes, while making them correspondingly illiquid, and it leads them to pile up substantial debts against those revenues and incomes.

This alone must set the stage for a depression if and when inflation stops. Because then the causes of the reduced demand for money balances are removed. At that point, people start trying to rebuild their cash holdings. As a result, spending and the velocity of circulation fall, with the further result that people's money revenues and incomes fall. The effect of this, in turn, is that they

cannot pay their debts. A substantial number of business and personal bankruptcies occurs.

The consequence of this, of course, is that the assets and capital of banks which have lent to such borrowers is correspondingly reduced, and many of them also fail. The failure of banks, of course, causes the money supply actually to be reduced, since the banks' outstanding checking deposits are part of the money supply. The reduction in the money supply then leads to a further decline in spending, revenue and income, and thus to still more bankruptcies and bank failures. The process feeds on itself, potentially to the point of eliminating all fiduciary media from the money supply and making the money supply equivalent to the supply of standard money alone.⁷⁷ The reduction in the quantity of money can be avoided only if the government is prepared to create additional fiat standard money to whatever extent may be necessary to guarantee the fiduciary media of the failing banks. But this lays the foundation for a still greater expansion in the supply of fiduciary media in the future.

This is the essence of the inflation-depression process. The critical factors are: artificial inducements to illiquidity and to a corresponding superinflation of revenues and incomes; the piling up of a mass of debt against these superinflated revenues and incomes; and then a contraction in spending, revenues, and incomes following the end of the inflation. The contraction phase leaves people with no means of paying the mass of debt they have accumulated, and can operate to produce a self-reinforcing downward spiral of deflation of the money supply.

The inflation-depression process is reinforced by the fact that inflation in the form of credit expansion causes malinvestments—investments which are profitable only on the basis of inflation itself. When the inflation comes to an end, the unprofitability of the malinvestments is revealed.

The onset of the depression is precipitated by the fact that inflation and credit expansion undermine the availability of real capital and thus of credit, too, in real terms. In particular, when credit expansion stops, a "credit crunch" develops. This is because the existing capital funds of many enterprises are made inadequate by the rise in wage rates and materials prices caused by the previous injections of credit in the form of new and additional money. The consequence is that firms requiring credit turn out to need more credit than they had planned on, while those firms normally supplying credit turn out to be able to supply less than had been counted on, and may even need credit themselves in order to meet the requirements of their own internal operations at these higher wage rates and prices. Thus, as the need for credit surges and as suppliers of funds become demanders of

funds, or at least supply less funds, firms that had counted on borrowing money, or on refinancing their existing borrowings, find that they are unable to do so. This causes insolvencies and bankruptcies. In this environment, as it becomes clear that the funds one had been counting on from others are not available, people's demand for holdings of money rises: it becomes necessary to liquidate inventories and other assets and to curtail expenditures, in order to have the funds available to meet one's obligations. In this way, the "velocity of circulation of money" falls.

These results can occur not only when inflation stops, but also when it merely slows down or even when it fails to accelerate sufficiently. To postpone the onset of a credit crunch, it becomes necessary to provide the victims of previous credit expansion with additional funds, in order for them to be able to pay the higher wage rates and materials prices caused by the previous credit expansion. Then still further inflation and credit expansion become necessary in order to overcome the resulting inadequacy of the funds of still others, possibly including the funds of the initial recipients of credit expansion, who perhaps are now themselves faced with unexpected increases in wage rates and materials prices. If at any point, the necessary additional credit expansion is not forthcoming, a credit crunch develops. If it is forthcoming, people soon begin to borrow on a larger scale, in anticipation of the possible inadequacy of funds in the face of higher wage rates and materials prices. If that additional demand for loanable funds is not met by still more credit expansion, the result is a credit crunch at that point. If it is met by still more credit expansion, the result is a still greater increase in wage rates and materials prices, which nullifies the value of the greater borrowing and requires still more credit expansion to avoid the onset of a credit crunch. Whenever the necessary additional credit expansion is not forthcoming, some firms find that they lack the funds they require, and thus a credit crunch develops.

The failure of inflation to accelerate sufficiently can also cause the demand for money for holding to increase, and thus velocity to decrease, insofar as the demand for money for holding has become unduly low based on the expectation of a more rapid acceleration of inflation than turns out to be the case. This consideration is relevant to the fall in the velocity of circulation that took place in the United States in the early 1980s. By the beginning of the 1980s, the height of the velocity of circulation corresponded to a growing expectation that the U.S. government would begin to inflate on a scale characteristic of Latin American countries. When the rate of inflation turned out to be much more modest, the demand for holdings of money increased in the United States, and

thus the velocity of circulation fell.

Finally, it should be realized that in order to produce a "credit crunch" and the onset of a depression, it is not necessary that credit expansion result in an actual rise in wage rates and materials prices. It is necessary only—as is inescapable—that it make wage rates and materials prices higher than they would otherwise have been. If wage rates and materials prices fail to fall, or fall by less than they would otherwise have done, the effect is still to render existing capital funds less adequate than they would otherwise have been and to create a need for more capital funds than would otherwise have been the case. As a result, in this case too, firms that would have been suppliers of capital funds in the loan market must become smaller suppliers, or even demanders of such funds. Thus, the basis is still present for the unexpected deficiency of credit that characterizes a credit crunch. These considerations are of great importance in considering the 1929 Depression, which came after a decade of relatively stable or even modestly declining commodity prices.

Gold Clauses and Prospective Inflation of Paper as the Cause of Deflation in Gold

It may help to shed light on the Great Depression of the 1930s to realize that there are circumstances in which the prospect of inflation can have the seemingly paradoxical effect of producing an immediate deflation. This is the case when the prospect of inflation takes place under a fractional-reserve gold standard, such as existed in the early 1930s, and at the same time the great bulk of debt contracts contain gold clauses. (Gold clauses define debts in terms of the obligation to pay a definite sum of gold. For example, prior to April 1933, the obligation to pay \$2,000 actually meant, according to most debt contracts in force in the United States, the obligation to pay approximately 100 ounces of gold, for it was explicitly stated that the dollars in the contracts were to be understood as representing gold at the rate of one ounce for every \$20.67.)

In such circumstances, whenever inflation causes a devaluation of the paper money against gold to a greater extent than the increase in the quantity of paper money, it reduces the ability of the paper money supply to pay debts in gold. In this sense, it constitutes a deflation. For example, if initially there are \$20 billion of paper money (including checkbook money) in existence in the United States, and these \$20 billion are convertible into gold, on demand, at \$20 per ounce, then this supply of paper is the equivalent of a billion ounces of gold. (Under a fractional-reserve gold standard, of course, there will not actually be a billion physical ounces of gold, backing the \$20 billion of paper, but only some fraction of this physical amount. However, the supply of paper money

is the *equivalent* of a billion ounces of gold in terms of current debt-paying power, so long as it is freely convertible into gold on demand at \$20 per ounce.)

If now, however, as the result of prospective inflation, and of the government's refusal to redeem the paper money for gold on demand, the price of gold were to rise, say, to \$40 per ounce, then the \$20 billion of paper would be devalued to the equivalent of only *half* a billion ounces of gold. If we view the supply of paper money not as a supply of "dollars," but as a supply of equivalents of gold ounces, then our assumed devaluation represents a halving of the money supply insofar as the money supply is composed of paper. For the paper money supply was a billion "gold-ounce equivalents," and now it is only half a billion "gold-ounce equivalents."⁷⁸ Such a devaluation would mean radically reduced "gold-ounce" sales revenues, while "gold-ounce" principal and interest charges remained the same. The prospect of such a devaluation must obviously mean the prospect of mass bankruptcies.

The prospect of such a devaluation and of its resulting mass bankruptcies must precipitate immediate bankruptcies, for lenders with funds coming due will not reextend credit in an environment in which its later repayment is made unlikely. Widespread immediate bankruptcies, of course, precipitate bank failures and a decline in the outstanding quantity of money. What is present here can be described as the prospect of future bad money driving present relatively good money out of existence.

On the basis of these considerations, I advance the hypothesis that the depression of the 1930s was intensified by the Federal Reserve's efforts to expand the quantity of money in order to reduce interest rates and finance large-scale government budget deficits. These efforts had the effect of creating the prospect of a devaluation of the dollar against gold and thus of making the honoring of gold-clause contracts correspondingly more difficult, with the result that they precipitated greater credit contraction and thus a larger number of immediate bankruptcies and bank failures, and, because of this last, a decline in the quantity of money. Seen in this light, the budget deficits of the Hoover administration must be regarded as profoundly and radically deflationary insofar as their financing necessitated the Federal Reserve's efforts to expand the supply of paper dollars and thereby threaten their gold value. By the same token, Roosevelt's 1932 campaign promise of reducing federal spending by 25 percent and balancing the budget turns out, had it been put into actual practice, to be exactly the right prescription for combatting deflation.

I hypothesize also that the policy of inflation which was pursued around the world, and the consequent devaluation of gold-standard currencies, was responsible for the radical reduction in the volume of international

trade which took place in the 1930s. For international trade had been conducted in gold or currencies regarded as equivalent to gold. This policy radically reduced the world supply of money when viewed as gold equivalents. In thus reducing the supply of internationally useable money, it reduced the volume of international trade.

(The principles present in this discussion apply to the devaluation of any currency in a situation in which substantial debts are payable in a different currency. For example, if an inflation of Mexican pesos precipitates a devaluation of the Mexican peso against the American dollar to a greater degree than the increase in the supply of pesos and spending in terms of pesos, while Mexicans owe substantial debts payable in dollars, the effect of the inflation of pesos is deflationary from the perspective of the ability of Mexicans to pay debts denominated in dollars. In the same way, the mere prospect of such a devaluation can render the Mexican government's policy of inflation deflationary from its very inception.)

8. Inflation as the Cause of Mass Unemployment

The fall in spending that takes place in the course of a depression causes mass unemployment, unless and until wage rates fall to the point of permitting the consequently reduced payroll funds to employ all who are able and willing to work. Since it is inflation that sets the stage for depressions, it is inflation that is responsible for the unemployment that accompanies them. In the absence of inflation and credit expansion, there would be no depressions and thus none of the mass unemployment that takes place in depressions, because the preconditions for a depression would simply not come into existence.⁷⁹

Given the existence of inflation, it is true that its continuation and acceleration can forestall the development of mass unemployment. But this no more makes inflation a means of preventing unemployment than narcotics are a means of preventing sickness and debilitation. The temporarily preventative effects both of inflation and of narcotics exist only in a context in which their prior use has created a dependency on them. Had they not been resorted to in the first place, the dependency would not exist. Stop their use, and after a painful interlude, the dependency disappears. And their use must be stopped, if utter destruction is not to result. When their use is stopped, it is their *use*, not the stoppage of their use, which must take the blame for the resulting mass unemployment in the one case and for the withdrawal symptoms in the other.

As we have seen, in the face of the existence of strong monopoly labor unions, inflation is ineffectual as a remedy for existing unemployment. For the unions will seize the opportunity of rising aggregate demand to raise wage

rates even in the midst of mass unemployment, and will thus prevent the growth in payroll funds from being accompanied by anything near a corresponding growth in the number of workers employed.⁸⁰ And, it should be recalled, those who are reemployed on the various make-work projects that almost always accompany any attempt to eliminate unemployment by means of inflation, are employed at a loss to the rest of the population, which must provide them with goods and services and receive nothing of corresponding value in return.⁸¹ On the other hand, in the absence of substantial monopoly labor unions, wage rates are free to fall and unemployment can be eliminated in this way.

There is only one case in which any kind of plausible argument can be made in favor of inflation as a remedy for existing unemployment. This is when a financial contraction/deflation has begun and in which no substantial downward adjustment of prices and wages has yet been made, and when there either are no substantial monopoly labor unions or, if there are, they are weakened to the point that they will not use the occasion of a rising aggregate demand to force up wage rates significantly. In this case, inflation, or more correctly the resumption of inflation, constitutes a restoration of the status quo ante, as it were, and is capable of achieving substantial reemployment. The conditions of this case appear to have been present in recessions in the United States since the early 1980s.

Even in this case, however, the essential problem remains that the policy of inflation continues, and with it, all of its destructive consequences. And to the extent that people come to expect that inflation will be resumed in such conditions, the effect is to prevent the downward adjustment of prices and wages that would eliminate the unemployment without any resumption of inflation. What occurs is nothing more than that the withdrawal symptoms are overcome by resuming the destructive narcotic, and the knowledge that the inflation narcotic is available prevents any step toward really solving the problem.

The government's readiness to resort to a resumption of inflation as the means of combatting unemployment guarantees the continuation of inflation with only the most minor of interruptions. Inflation goes on both when unemployment is a problem and when it is not a problem. It sets the stage for a financial contraction/deflation and thus mass unemployment as soon as the government makes any serious effort to stop or reduce it, and then, because of this, no sooner does the government make such an effort than it comes under mounting pressure to abandon it and return to its policy of inflation. If inflation is ever to be eliminated, the government must lose the power to inflate even in conditions in which doing so can reduce unemployment. Unemployment must be elimi-

nated through a fall in wage rates and prices.⁸²

Sooner or later, of course, even in the midst of continuing and accelerating inflation, substantial unemployment develops in any case. It occurs because of the tendency of real wage rates to fall as the result of inflation and because of efforts to prevent this fall by forcing wage rates to rise fully as rapidly as prices, without benefit of the necessary increase in the demand for labor.⁸³ Even more important is the fact that as inflation becomes more extreme, the potential for sudden mass unemployment is created by efforts merely to moderate the inflation, and even by the failure sufficiently to accelerate it.

For example, if the quantity of money and aggregate demand have been growing rapidly enough to raise wages and prices, say, by 50 percent a year, and the government decides that it wants to moderate the inflation to the point that wages and prices rise only by 25 percent a year, its action is capable of causing mass unemployment. This will occur simply by virtue of wages and prices continuing to rise for a time at their previous rate, on the basis of sheer inertia, as it were. In the face of a relatively "modest" 25 percent rise in the demands for consumers' goods and labor, the effect of increases in the price and wage level temporarily continuing at a 50 percent rate is a one-sixth decline in the quantity of consumers' goods purchased and a one-sixth decline in the number of workers employed. This is because $\frac{5}{4}$ times the demand, when divided by $\frac{6}{4}$ times the price or wage level, can purchase only $\frac{5}{6}$ times the quantities.

Similarly, in conditions in which the rise in prices and wages discounts a substantial acceleration in the increase in aggregate demand that fails to materialize, mass unemployment will result. For example, if aggregate demand has been growing at a 50 percent annual rate and wages and prices begin to rise at a 75 percent annual rate, in anticipation of aggregate demand growing at 75 percent, and then aggregate demand fails to grow more than 50 percent, a comparable degree of unemployment will be created. The same kind of results occur, of course, in conditions in which the demand for money for holding has fallen in anticipation of a degree of inflation that does not materialize, which then leads to a rise in the demand for money for holding. A situation describable by one or more of these three patterns of the development of mass unemployment in the midst of inflation occurred, for example, in Uruguay in the late 1960s, when the unemployment rate reached 28 percent at the same time that prices were rising at an annual rate of 61 percent.⁸⁴

9. The Inherent Accelerative Tendencies of Inflation

The potentially most devastating consequence of inflation is that, once begun, the process tends to accel-

ate. The ultimate stopping point of the acceleration is that the inflated currency loses its acceptability. This occurs when people realize that between the time they accept it and even the earliest possible time they can spend it and thus pass it on to someone else, they will have suffered a substantial loss in buying power. At that point, they refuse any longer to accept it in exchange for their goods and services, and turn instead to barter if necessary. The inflated currency loses its character as money and ends up being dumped in the streets and down the sewers, as just so much litter.

In his seminar, von Mises used to describe the acceleration of inflation as going through three phases. In the first phase, people observe that prices are rising but still believe that the rise is temporary. They are willing to increase their holdings of money, in the conviction that prices will one day come down. In the second phase, people have come to the conclusion that prices will never come down, but will go on rising. In this phase, their attitude is described by the man who says, "I do not need a new refrigerator this year, but I will need one next year. I will buy it this year, however, in order to avoid having to pay a higher price for it next year." In the third and final phase of inflation, the attitude of people is described by the man who says, "I do not need a new refrigerator now and never expect to need one, but I will buy one nonetheless, because it is better to own anything than this rapidly depreciating money." This last phase represents what is described as the "flight into real values."⁸⁵

Inflation tends to accelerate for a variety of reasons. One is that the underlying premises which lead to the policy of inflation in the first place—namely, the alleged helplessness of the individual and the alleged omnipotence and benevolence of the government—logically call for more and more rapid inflation as time goes on. As we shall see, two factors closely related to this are that inflation itself creates problems whose solution is perceived as requiring still more inflation, and that the stimulative effects of any given rate of inflation tend to wear off and to require a more rapid rate of inflation to maintain them.

Both of these phenomena are present in the very fact that inflation tends to raise the velocity of circulation. So long as the velocity of circulation is rising, the rate of increase in the volume of spending in the economic system is greater than the rate of increase in the quantity of money. But once the velocity of circulation stabilizes at any given higher level, the rate of increase in the volume of spending necessarily falls to that of the rate of increase in the quantity of money alone. To maintain the previously higher rate of increase in the volume of spending, a more rapid rate of increase in the quantity of money is now necessary, which, in turn, tends to be accompanied

by a still higher velocity of circulation of money, leading, of course, to the same result and the need for a still more rapid increase in the quantity of money later on. In addition, as the result of any stabilization of velocity after a sustained period of rise, the rate of profit is almost certain to fall, inasmuch as it will now reflect a lesser rate of increase in spending. Its fall, furthermore, operates to diminish the gains inflation provides to stockholders and other business debtors at the expense of bondholders and other business creditors. These gains meanwhile are also tending to be reduced by a rise in the rate of interest toward any given rate of profit.⁸⁶ Thus, an acceleration of inflation is called for to maintain the rate of profit, and a more rapid acceleration to maintain any given ratio of excess of the rate of profit relative to the rate of interest. These accelerations must be indefinitely repeated if the rate of profit is not to be allowed to fall and if its relationship to the rate of interest is to be maintained.

Of course, there is nothing inevitable in the acceleration of inflation. It can be interrupted; indeed, inflation can be stopped altogether. But in order to do either of these things, the willingness must exist to bear the temporary painful consequences. The accelerative tendencies of inflation all come down to the fact that there are such consequences. If the willingness to bear them is lacking, then inflation can be presumed continually to accelerate.

The Welfare-State Mentality

The logic of the welfare-state mentality is capable all by itself of resulting in unlimited inflation. If it is believed that the government is a real-life Santa Claus, indeed, a benevolent deity, and that its inflation-financed deficits are the source of free benefits, then there is no logical stopping point to the size of the deficits and the amount of the inflation used to finance them—given the fact that the government has the power to inflate.

If, for example, it is believed that the government has the power to provide free high-school education, then why not free college education? If it has the power to provide free medical care to people over sixty-five years of age, then why not to everyone? If it has the power to provide some people with low-cost housing, then why not more people?—why not everyone? If it can make it possible for people to retire at age sixty-five, then why not at age sixty, or even fifty-five?

Even under the Reagan administration, which appeared to manifest a substantial opposition to further growth of the welfare state, the corrupting influence of the ability to inflate never diminished. On the contrary, it thoroughly undermined efforts to end the growth of the welfare state and turned the desire for lower taxes and a stronger national defense into causes of more rapid infla-

tion. The Reagan administration, at least in its early years, rightly regarded the proper function of the federal government as that of providing national defense, not public welfare. It espoused a philosophy of limited government and low taxes. Yet the government's ability to inflate made it possible to increase the defense budget and lower taxes without making any reduction whatever in the amount of welfare state spending. The result was that the Reagan administration simply added its increase in the defense budget, and its tax reductions, to a still growing level of welfare-state spending, and produced unprecedented peacetime budget deficits. These deficits required and received the support of very high rates of inflation—for example, a 16.9 percent increase in the money supply in 1986, following an 11.1 percent increase in the money supply in 1985.⁸⁷

Throughout the Reagan years, the premise persisted that there is no limit to what the government can accomplish, if only it is willing to spend enough money. The great majority of people continued to believe all along that an economically insignificant city—Washington—which is utterly lacking in industry and is not a center of commerce or the performance of any other economic service, is nevertheless somehow capable of “bailing out” the economic system. “Washington” was and is thought to be capable of rescuing major companies and entire industries and undertaking the economic redevelopment of such major cities as New York, Philadelphia, Detroit, and Cleveland, and even that of whole states and entire geographic regions.

Nothing could be better evidence of the delusion inflation fosters, that it is the government that supports the people instead of the people who support the government, than the prevalence of such beliefs. “Washington” is seen as capable of achieving all these miracles for the simple reason that its ability to inflate allows it to spend money without first having to collect that money from the people. If not for this, it would be obvious that “Washington” can give nothing that it does not first take away, and thus, whenever it acts to help any individual or group, it is intensifying the hardship of other individuals and groups, and, indeed, causing losses substantially greater than any gains it may provide. For it not only takes from A to give to B, but in the process it reduces the incentive and the ability to produce.

Whatever the opposing influence of the Reagan administration, the welfare-state mentality has now been reenthroned. In the midst of massive budget deficits, and the shedding of rivers of crocodile tears over them, the last few Congresses have busied themselves with such measures as expanding the Medicare system and embarking on federal support for child-care facilities. And, not very long ago, the administration of President Clin-

ton was narrowly prevented from imposing a vast increase in government financing of medical expenses, which, had it been enacted, would almost certainly have turned out to be greater in cost than any new government program since social security.

Inflation to Solve Problems Caused by Inflation

The expressions “bail out” and “rescue” suggest what is perhaps the most important reason that inflation tends to accelerate. This is the fact that the very destruction and suffering that inflation causes makes still more inflation seem necessary and desirable. Inflation becomes the means of alleviating the consequences of inflation. It is a tool, an evil, destructive tool, but one whose immediate, visible effects for the user and for the groups on whose behalf it is used seem desirable. Thus, the more and the greater are the problems it creates, the more it tends to be used. Again, the analogy to drugs is very apt. Someone begins taking drugs as a means of alleviating his feelings of inadequacy. The effect of the drugs is soon to make him feel still more inadequate. And the apparent solution is then to increase the dosage.

The fact that major cities and industries need “bailing out”—which, of course, the government would finance largely on the basis of an increase in the quantity of money—is itself mainly the result of years of inflation and the consequent systematic overstatement of profits, leading to the taxation and consumption of funds required for the replacement of assets. It is a consequence of all of the destructive effects of inflation on saving and capital formation. Similarly, demands for ever more government aid to the elderly, and the inflation that must be resorted to in order to finance those demands, are largely the product of previous inflation, which has wiped out the value of pensions and savings. In the same way, demands for government support of the home-mortgage market, and the inflation required to finance it, are the result of the destruction of mortgage credit brought about by previous inflation.

When inflation goes far enough actually to reduce the ability to produce, the real revenues of the government begin to decline. This, together with the increasing demands being made upon the government as the result of the same process of economic decline, almost inevitably results in a still further acceleration of inflation.

The apparent need to inflate is further compounded to the degree that the rise in prices reaches the point of substantially reducing the buying power of the government's tax collections, which are largely based on incomes and transactions of the recent past. The more rapid the rise in prices, the greater is the reduction in the buying power of such tax receipts, and thus the greater the apparent need of the government to rely still more heav-

ily on the printing press as the source of its funds. And, as previously pointed out, the apparent need to inflate is greatly increased when the day comes that private investors reach the conclusion that they must lose by purchasing government securities, and thus stop doing so, leaving the government's printing presses to make up for their withdrawal.⁸⁸

The government is motivated to accelerate inflation not only for all of the above reasons, but, of course, also to paper over developing "credit crunches" as well as to overcome the previously described "profit squeezes" that must result from the stabilization of the velocity of money at any given higher level.⁸⁹

Recessions as Inflationary Fueling Periods

Paradoxically, given the ability to inflate, even government efforts to end or reduce inflation can serve to accelerate it. The government begins by cutting back on inflation. But then a recession develops: insolvencies and bankruptcies appear; unemployment starts to increase. Now the government becomes frightened. Before the recession goes too far and turns into a full-scale depression, it reverses itself and accelerates the inflation. As a result, cash holdings relative to spending are built up on the basis of newly created money rather than on the basis of a decline in spending. At the same time, the injection of the new and additional money brings an end to the insolvencies and bankruptcies and mounting unemployment. Finally, once it is recognized that the danger of a depression has passed and that the policy of inflation is back in place, the money created to turn the recession around comes pouring out into the spending stream. In this way, even recessions end up serving as inflationary fueling periods.

Indexing and the Wage and Interest Ratchets

As people become aware of the consequences of inflation, they take steps to protect themselves. The use of price indexes is one very popular method.

It should be realized that price indexing does not provide any means for dealing with the problem of lags between the rise in the prices one must pay and the prices or income that one receives. At most it can enable an individual to catch up with the rise in prices. But it does not compensate people for the loss of purchasing power they experience in the intervals before catching up. Moreover, the widespread use of indexing, by operating to make prices rise automatically by the same percentage, undermines the functioning of the price system, which depends precisely on the *unevenness* of price changes.

Despite their shortcomings, inflation spawns the use of price indexes. They appear more and more in employment contracts, where they require periodic increases in

wages in line with the rise in prices. Some years ago in the United States, social security payments became tied to a cost-of-living index. More recently, income tax brackets have been tied to the movement of prices: to the extent that the rise in individuals' incomes does not exceed the percentage by which prices rise, their tax bracket will not be increased. In the years ahead, it is possible that depreciation allowances will be tied to a price index. The payment of interest on government bonds and the computation of interest income for tax purposes might also some day include adjustments for the rise in prices.

All of these measures of protection against the effects of inflation tend to accelerate inflation, by creating further problems whose solution appears to be still more inflation. For example, to the extent that wages are increased merely because prices rise, that is, in the face of a given demand for labor, unemployment tends to develop. If the government wishes to avoid the unemployment that wage indexing can cause, then it must see to it that the wage increases are accompanied by further increases in the quantity of money. In that case, wages can increase and the increases can be passed along in the form of further price increases, which then serve as the basis for further wage increases. By providing the money to accommodate a wage-price spiral, the government can be led into an extreme and rapidly accelerating inflation—at each step pouring ever more money into the market in order to avoid the unemployment that would result from not accommodating the wage-price spiral. This has been the situation in Israel and Argentina and many other countries.

The indexation of the government's expenditures, such as social security payments, and the indexation of its tax revenues, operate to enlarge its expenditures and reduce its revenues. The result is a tendency toward greater deficits and thus more rapid creation of money to finance the deficits.

Even apart from wage indexing, there is a powerful tendency for inflation to accelerate in the government's efforts to avoid unemployment. For example, the labor unions may begin very modestly—seeking to raise wages by, say, a mere 2 percent above the level a free market would provide. The effect of their action is either the development of an addition of roughly 2 percent to the unemployment rate or to lead the government to choose to increase the quantity of money by an additional 2 percent, to make the demand for labor keep pace with the rise in wage rates.

If, as is likely, the government chooses to increase the quantity of money by an extra 2 percent, then no additional unemployment develops, but prices rise by an additional 2 percent. The unions now feel cheated. Their

wage increase in the previous year has been eaten up by price increases. Perhaps for a number of years they will continue to ask for just an additional 2 percent. If so, the same story will continually repeat itself. Sooner or later, however, the unions will come to take a 2 percent rise in prices for granted. At that point, in order to obtain a 2 percent real improvement, they will begin to ask for wage increases of 4 percent. If the government increases the quantity of money sufficiently to accommodate this higher rate of wage increase, then additional unemployment will again be avoided, but now prices will begin to rise on the order of 4 percent a year instead of just 2 percent a year.

Once again, the scenario may be repeated several times. But eventually, the unions will conclude that prices can be expected to rise by 4 percent a year, and that in order to obtain a gain in real wages of 2 percent, they must demand wage increases of 6 percent. If the government continues to accommodate the unions by increasing the quantity of money more rapidly, their wage demands will rise to 8 percent, then 10 percent, and so on. In a word, there is an upward ratcheting of wage demands, with each higher level of wage demands (provided it is accompanied by the necessary increase in the quantity of money) serving to establish a higher level of increase in prices, on the basis of which wage demands are raised further.

At some point along the way, a process that can be described as double discounting emerges. The unions conclude that prices will not rise merely at some given rate, but can be expected to rise at an *increasing* rate. At this point, in order to obtain whatever increase in real wages they are after, they begin to demand wage increases equal not only to the rate at which prices have been rising up to now, plus the real improvement they seek, but wage increases equal to the higher rate at which they expect prices to rise over the life of their employment contracts, plus the real improvement they seek. This represents an *acceleration in the acceleration* of wage and price increases. And from here, still further acceleration in the acceleration develops, as expectations concerning the rate of acceleration start to increase. Thus, wage demands of 4 percent over the previous rise in prices are appropriate as a means of seeking a 2 percent real improvement only if the rate of price increases advances at 2 percent a year. But now, as the result of the demands for more rapid wage increases (always assuming, of course, accommodation by a more rapidly increasing quantity of money), prices will begin to rise with an acceleration of 4 percent a year instead of just 2 percent a year. Soon the unions will take such acceleration for granted and begin to accelerate their wage demands by 6 percent, then 8 percent, and so on. And thus,

wages and prices begin skyrocketing upwards—10 percent a year, 14 percent a year, 20 percent a year, 28 percent a year, and on and on.

A similar process of upward ratcheting and acceleration takes place in connection with interest rates. The rise in prices that inflation causes reduces the real rate of interest received by creditors. In order for lending to be worthwhile, creditors need to receive higher rates of interest, which reflect the rate at which prices rise. But, as we have seen, no sooner do creditors begin to receive such rates of interest, than the special profit inflation provides to borrowers is removed. Moreover, inflation makes it a matter of virtual self-preservation for borrowers to gain at the expense of lenders, because if they do not, then, on an after-tax basis, their incomes cannot possibly keep pace with the rise in the replacement prices of their assets.⁹⁰ As a result, the borrowers find the rise in interest rates oppressive and demand a more rapid rate of inflation and credit expansion, both to reduce interest rates and to provide the revenues and profits with which to make any given level of interest rates payable. This problem becomes more intense, the greater inflation becomes, because the overall real rate of return on capital as such is all the more reduced, making the plight of the borrowers correspondingly more desperate in the absence of an ability to be compensated at the expense of the lenders.⁹¹

A succession of rounds of rising inflation and rising interest rates to compensate the creditors may ensue. But each time, the higher level of interest rates turns out to be inadequate in the face of still more rapidly rising prices. Finally, the day arrives when creditors conclude that no rate of interest, however high, will protect them, because the rate of price increase will be still higher. At that point, all private credit begins to disappear. Private citizens stop lending not only to the government but also to each other. At this juncture, a great quantum leap in the rate of inflation can easily take place. For the government may now attempt to replace the dwindling supply of private credit, provided out of savings, with credit provided out of newly created money. Indeed, this phenomenon exists, though on a comparatively small scale, as soon as any of the citizens become aware of what is happening and therefore cease to lend money. From this time on, there is a reduction in the supply of loanable funds that the government is motivated to make up for through policies of more rapid inflation.

The Current State of Inflation

As I have indicated, all of the above forces operating to cause inflation to accelerate are *tendencies*. Like anything else that is subject to human choice, their operation is not absolutely inevitable or inescapable, and certainly

not in any given short period of time. Their presence very well describes the period 1933-1980 in the United States. In 1981 and 1982, however, the U.S. government refused to provide the accelerated increase in the quantity of money that the markets had come to expect it to provide.⁹² Instead, it inaugurated a prolonged and severe recession—some would say the first depression since the 1930s. It allowed unemployment to increase and bankruptcies to occur to the point where people gave up the expectation of rapidly accelerating inflation and became willing to sell their goods and services at much lower rates of price increase than had prevailed before. Hence, the conviction developed that inflation was now “under control.”

The result of the government’s action in those years was actually to create a good deal of *deflationary* psychology. Many people came to fear that the legacy of enormous debt burdens and illiquidity left by inflation would drag the economic system into a sharp contraction of spending and successive waves of bankruptcies and bank failures, which the government would be powerless to stop. And, in truth, it must be admitted that major deflationary *potential* has existed and really does exist in the economic system. The collapse of real estate prices, the resulting failure of large numbers of savings and loan associations and savings banks, whose major asset was real estate loans, and the resulting virtual bankruptcy of the Federal Savings and Loan Insurance Corporation, all provide ample evidence of this. Further and even stronger evidence was provided by the precarious condition of many commercial banks and the virtual exhaustion of the resources of the Federal Deposit Insurance Corporation.

If, however, anything that is subject to human choice can be certain, it is that no contemporary government, with its unlimited power to create money, will allow a major depression to develop as the result of any failure on its part to increase the quantity of money. No matter how many billions or tens or hundreds of billions of dollars it takes to rescue the mass of debtors and to keep the level of spending on an upward course, the government possesses the means to create those billions.⁹³

Consistent with this observation, from 1982 to early 1987, in order to prevent the debt crisis from deepening and in order to reduce the unemployment rate, the government embarked upon a reacceleration of inflation. Because the reacceleration came in the midst of a relatively noninflationary or even deflationary psychology, the result was that the new and additional money was held more tightly than it otherwise would have been. The fact that inflation psychology had been greatly diminished encouraged the government to reaccelerate inflation very sharply in 1985 and 1986, in the conviction that it could do so without experiencing the consequences of

inflation. As previously mentioned, the money supply was increased in those years by 11.1 percent and 16.9 percent respectively.⁹⁴ So long as prices were not rising rapidly and the public was thus not much concerned with inflation, the government felt free to expand the quantity of money at these much more rapid rates.

One of its objectives in rapidly increasing the quantity of money was a major reduction in the foreign exchange value of the dollar, which had continued to increase until well into 1985, as a consequence of diminished inflationary expectations in the United States. This deliberate reduction of the dollar’s foreign exchange value took place in the mistaken belief that it would stimulate exports and at the same time discourage imports, thereby reducing America’s allegedly “unfavorable” balance of trade. A cheaper dollar, it was believed, would make American goods correspondingly cheaper to foreign buyers, who had to buy dollars in order to be able to buy American goods. By the same token, a cheaper dollar was thought to mean that foreign goods and services would be that much more expensive to Americans, who had to buy the foreign currencies in order to buy foreign goods and services, and who now would have to pay that much more for those currencies.

What the supporters of this idea overlooked was that the virtually inevitable consequence of the much higher rates of increase in the money supply in 1985 and 1986 was an acceleration in the rate at which prices rose in 1987 and 1988. This more rapid rise in prices operated to price American exports out of the market, and to encourage imports, thereby confirming what every real economist knew from the very beginning, which was that the government’s policy of inflating in order to reduce the foreign exchange value of the country’s currency was contrary to purpose and an exercise in futility, precisely because it would cause American prices to rise more rapidly.

In 1987, acting no doubt in fear that it was inflating too rapidly, the government adopted a sharply less inflationary policy, which resulted in a relatively modest increase in the money supply of 3.5 percent for that year.⁹⁵ This was followed by rates of increase in the money supply of 4.9 percent in 1988, less than 1 percent in 1989, and barely 4 percent in 1990, with most of the increase in 1990 occurring in the last portion of the year.⁹⁶

Not surprisingly, after years of having become adjusted to substantially more rapid rates of increase in the quantity of money, the extremely modest rate of increase in the money supply of 1989 and most of 1990 operated to bring about a sharply higher demand for money for holding, a correspondingly lower velocity of circulation of money, and a general inability to repay the great mass

of outstanding debt—i.e., the government drove the economy to the brink of a major depression. Then, as the threat of depression became clear, the government returned to the policy of more rapid increases in the quantity of money, and brought about a rate of increase of almost 9 percent in 1991, more than 14 percent in 1992, and more than 10 percent in 1993. Overall, from the end of 1990 to the end of 1993, the compound annual rate of increase in the money supply was approximately 11 percent.⁹⁷

In their response to the depression or near-depression of 1990–1992, the government’s policy makers divided into two camps. A relatively moderate group of inflationists, led by Federal Reserve Chairman Alan Greenspan, and often mistakenly thought of as supporting “tight money,” favored increasing the quantity of money at whatever rate was required to overcome the growing deflation/depression psychology that characterized 1991 and 1992. Once it became clear that that was accomplished and that signs could be found that price increases were starting to accelerate as the result of the rapid infusion of new and additional money into the economic system, this group favored going back to sharply curtailing the increase in the quantity of money. Inasmuch as this group currently controls the actions of the Federal Reserve System, it has been able to have its way, and as of October 1994, the annualized rate of increase in the quantity of money since the beginning of 1994 has been little more than 2 percent.⁹⁸ This substantial deceleration in the rate of increase in the money supply has been accompanied by a succession of increases in short-term interest rates, which the very rapid increase in the quantity of money in the face of widespread deflationary psychology had driven to levels not seen since the early 1950s.

The other group of government policy makers, which includes the president and his advisers, as well as key congressmen and senators in a position to introduce legislation concerning the Federal Reserve System, such as the chairman of the House Banking Committee, favors no substantial deceleration in the rate of money supply increase and, indeed, at least by implication, favors a further acceleration in the rate. Both of these conclusions follow from the fact that the members of this group have become alarmed at each of the increases in short-term interest rates that has taken place this year and have opposed those increases. They apparently are either unaware or unconcerned that given the rise in sales revenues and profits, and thus in the demand for loanable funds, that the increase in the quantity of money and volume of spending has brought about, the only way that interest-rate increases could have been avoided would have been by virtue of meeting the additional demand for loanable funds with a further and progressively growing increase in the supply of loanable funds provided out of

new and additional money.⁹⁹ Interest rates have risen because the Federal Reserve has been unwilling to provide the banking system with the additional standard money reserves to make that possible. In contrast, the only point at which the members of this group appear willing to consider the need for slowing down the increase in the quantity of money is when confronted with the existence of rapidly rising prices as an already established fact. Until that time, they believe, inflation is not a problem—it doesn’t even exist.

Both groups of government policy makers confuse inflation with its consequence, rising prices, and are thus prepared to stop it only after it is too late. In this virtual theater of the absurd, the more extreme inflationists criticize the less extreme inflationists for seeing inflation that isn’t there yet and responding to a problem that allegedly either doesn’t exist at all or does not yet exist on a sufficient scale to warrant action of any kind.

When all is said and done, what distinguishes the two groups of today’s government policy makers is only the degree to which they are prepared rapidly to inflate. For today’s “moderate” inflationists, a rate equivalent to 11 percent compounded for three years is enough for a while. For the more radical inflationists nothing is enough, at least until prices are rapidly rising all around them. At that point, they will admit the existence of a problem. The “moderate” inflationists, it should be noted, have recently been losing ground to the more radical inflationists, as the result of appointments to the Federal Reserve Board made by President Clinton.

Whichever group prevails in the year or two ahead, the government’s response to the depression or near-depression of 1990–1992 confirms that recessions and even virtual depressions nowadays do indeed represent inflationary fueling periods. Decades of inflation have so reduced the demand for money for holding and so encouraged indebtedness that all efforts seriously to end inflation serve to bring on a major depression. In the face of that prospect, the government recoils and turns the impending depression into a new inflationary fueling period. The only difference between the conservative inflationists and the radical inflationists on this score is that the conservatives hope to be able to stop the process before it goes too far. They hope to be able to keep the fuel that has already been put out there from being ignited into a major rise in prices, while the more radical inflationists do not hesitate to guarantee such ignition by continuing to pour out the fuel.

Although the conservative inflationists currently control the Federal Reserve System, it should not be expected—assuming that they are able to retain control in the first place—that they will adhere to their program of curtailing the increase in the quantity of money. That

policy, when pursued in 1988, 1989, and 1990, ended up costing President Bush his reelection. It will be substantially harder to pursue the next time, even if, perhaps especially if, a conservative occupies the White House and wants to be reelected. Thus inflation must continue on a substantial scale even under conservative administrations and conservative money-supply managers. This conclusion is further confirmed by the fact that prices rising at a rate of 3 percent a year are now considered “acceptable” and as evidencing the lack of a problem of inflation, even though in a generation such an annual rate of increase must succeed in more than doubling prices and thereby halving the buying power of all incomes and assets that are contractually fixed in dollars.

Only when inflation results in prices rising rapidly enough to evoke widespread public concern and thus to become a major political issue, can the government expect to have substantial public support for a policy of reducing its inflation for any prolonged length of time and at the risk of substantial unemployment. And even then, sufficient public support is by no means guaranteed, as the experience of all the Latin-American countries shows.

Given our present monetary system, the only way the government can continue to keep inflation within the limits set by the Reagan and Bush administrations is if every few years it were willing to provoke a recession at least as severe as the last two. In essence, it would have to return to the boom-bust conditions of the pre-New Deal days, in which limited inflations were always brought to a sharp halt and followed by a depression. Then it could reestablish something of the old mentality of “what goes up must come down” in reference to prices, and of fear of becoming overextended in reference to size of debt and adequacy of cash holdings.

However, there is an essential difference between the conditions of the present and those of the pre-New Deal days. In the days before the New Deal, the existence of a gold standard *forced* the government to bring inflation to an end. Today, there is no gold standard and thus nothing to force the government to end or even limit inflation. Indeed, the gold standard was abolished precisely in order to make unlimited inflation possible. In the absence of a gold standard, it seems extremely unlikely that today’s voting public will be willing to see unemployment go to 10 or 11 percent every few years in order merely to reduce the rise in prices by a few percent for a limited time.

In view of the nature of the roots of inflation and of the enormous corrupting influence of the power to inflate, it seems likely that in retrospect the 1980s and early 1990s will turn out to have been merely an interlude in the process of accelerating inflation. A real solution to

the problem of inflation requires depriving the government of the *ability* to inflate.¹⁰⁰

Inflation and the Potential Destruction of the Division of Labor

As I have said, the potentially worst effect of inflation is acceleration to the point of depriving the inflated monetary unit of its acceptability and thus of its character as money. If it accelerates to that point, inflation is capable of destroying a division-of-labor society and with it, the whole of modern material civilization. As explained earlier in this book, the existence of money is an essential precondition of the existence of a division-of-labor society.¹⁰¹ In destroying the existing monetary unit, inflation is capable of destroying the existence of money as such.

Whether or not the destruction of a given monetary unit is tantamount to the destruction of money itself, depends on the possibility of replacing the monetary unit that has been destroyed, with a new monetary unit. A new monetary unit cannot simply be decreed into existence—it would have no better chance of acceptance than “Monopoly” money or any other play money. In order to enjoy the universal acceptability that is essential to money, the new monetary unit must already have been established as a virtual money. In order for people to be willing to accept the new money, they must have the expectation that they can easily reexchange it with others for all the goods and services that they desire. This means that the new money must already virtually be money. If such an alternative money does not exist, then the only way the destruction of the monetary unit can be followed by the emergence of a new monetary unit is on the basis of a new universally accepted medium of exchange developing out of the conditions of barter.¹⁰² In the interval in which this development takes place, however, which could be very considerable, the economic system would be without money and thus could not sustain the extensive division of labor on which modern material civilization depends.

The collapse of the assignats in 1796, in revolutionary France, was followed by the reappearance of gold and silver coin, which had been the money of France prior to the Revolution and had continued to be the money of the surrounding countries. The reappearance of gold and silver coin also followed the earlier collapse of the American continental currency in our own Revolutionary War, and the subsequent collapse of the Confederate currency in our Civil War. The collapse of the German mark in 1923 was followed by the introduction of a new mark redeemable on demand in American dollars, which, in turn, were redeemable on demand in gold. In these cases, which can be taken as characterizing all modern hyper-

inflations, a new monetary unit could quickly take the place of the unit that had been destroyed, because it either was itself already established as money or was redeemable on demand in an already established money. In the case of the new marks, every German who took them knew that he could use them to buy whatever dollars could buy.

It cannot be stressed too strongly that the ability quickly to replace the monetary unit that has been destroyed has existed in all modern hyperinflations only because these hyperinflations either took place in an environment in which an alternative money already existed in the countries concerned, or occurred only in very limited areas. In the latter case, the existence of money was essentially undisturbed in the rest of the world and in particular in the areas with which the affected countries carried on extensive trade relations.

It is a different story when a hyperinflation takes place over a very extensive territory and the possibility of replacing the monetary unit that has been destroyed, with a new monetary unit, is not present. In that case, the existence of money as such is destroyed, and with it the basis of any extensive division of labor.

History appears to provide at least one major example of this kind: the collapse of the Roman Empire. A prominent history text records:

Debasement of the Roman coinage had begun as early as the reign of Nero. But in the third century, as a result of mounting inflation, widespread hoarding of specie, and sharply reduced revenues, the emperors resorted to reckless adulteration of the imperial coinage to meet their military and administrative costs. As a result, distrust of new currency was widely manifested, by individuals as well as by banks. Ultimately the government refused to accept its own coinage for many taxes and insisted on payment in kind.¹⁰³

Gold and silver were prohibited from reemerging as money (which they might easily have done), because of the Roman government's insistence that they not circulate at a premium over its debased coinage.¹⁰⁴ At the same time, all private hoards of the precious metals were subject to confiscation by the Roman government, which was eager to use them for its own, immediate purposes.

In these ways, the Roman government destroyed the existence of money in its territory, and with it the most extensive division of labor in the history of the world prior to modern times. Among the consequences was the loss of the ability to have a paid, professional army, capable of being supplied with provisions purchased with money. The impregnable legions of Rome's heyday had to be replaced with a militia of farmers, who lived along the frontier, in virtual economic self-sufficiency, and who were expected to leave their farms and go out and fight when the need arose.¹⁰⁵

Given the absence of a gold and silver money ready

to take their place, a simultaneous hyperinflation of all the major paper currencies of the present-day world would have the effect of destroying money as such. Such a hyperinflation must be considered a real possibility, in view of the fact that all the countries of the world pursue deliberate policies of inflation, all of which are subject to the inherent forces of acceleration described above. Furthermore, there is a distinct pressure on each country to inflate more or less in pace with its major trading partners, in order to prevent its currency from sharply appreciating relative to theirs, thereby encouraging a so-called unfavorable balance of trade.

But even if hyperinflation did not occur simultaneously in all the major countries, it could still have the potential for destroying the existence of money in a country whose economy is as large relative to the world's economy as that of the United States. While Weimar Germany could introduce a new mark based on redeemability in American dollars, it is doubtful that the United States could introduce a new dollar based on redeemability in German marks. The reason is simply the relative size of the two economies. The currency of a vastly larger economy can serve as the foundation for the introduction of a new currency in a country with a much smaller economy. But it is doubtful that the reverse can be true. The United States had the ability economically to rescue a country the size of Germany, including the provision of sufficient dollars to back a new German currency. The provision of dollars to back a new mark neither drew away so many existing dollars from other uses, nor required the creation of so many new and additional dollars, as to create a major problem for the United States. But Germany does not have the means of economically rescuing the United States, nor therefore of providing sufficient marks in real terms for backing a new dollar. The American people could not expect, as could the German people, to be able if necessary to use their new money to obtain a mass of goods from outside the country. The resources to provide the goods would simply not be present. The provision of marks to back a new dollar would require either the drawing away from other uses of so many marks or the creation of so many new and additional marks, as to create a problem of overwhelming dimensions for Germany. The same essential points, of course, are equally applicable to Japan as a potential source of a new dollar.

Thus, hyperinflation in the present-day United States would have the potential for the destruction of money as such in the United States, and with it, the material civilization of the United States. For the modern Western World in general and for the United States in particular, inflation has destructive potential on a scale not seen since the onset of the Dark Ages.

PART C**GOLD****1. Freedom for Gold as the Guarantee Against the Destruction of Money**

The solution for every aspect of the inflation problem lies in gold (and silver). The widespread ownership of gold and silver coins by American citizens, and the concomitant willingness of large numbers of Americans to accept them in payment for their goods and services, would be a guarantee against the destruction of money through hyperinflation. It would mean that a new money would be ready to take the place of the present paper money, should the latter ever be inflated into extinction.

However remote the possibility of hyperinflation and the destruction of money in the United States may appear at the moment, it should be kept in mind that the time required for such a possibility to loom as large as it did in 1979 and 1980 is no greater than the time that was required to make it recede. In other words, in the space of just a very few years conditions are capable of undergoing large and unexpected change, with the result that what may seem so unlikely at the present moment as scarcely to be worth consideration, can be upon us relatively quickly and unexpectedly. Given the nature of the present monetary system, all of the basic elements are in place that are required to make hyperinflation possible and thus to make the destruction of money possible. Because of the utter devastation that would then ensue, it is very definitely worth taking precautions against any such possibility, which, of course, is what extensive ownership of gold and silver coins would provide.

As I explained in Chapter 12, in a period of rapid inflation the market itself tends to remonetize gold and silver through their growing use as “inflation hedges.” The imperishability, homogeneity, and divisibility of gold and silver, coupled with their existing high value in a small bulk, based on their utility and rarity as ordinary commodities, make them ideally suited for use as inflation hedges by most people. Their minimal costs of storage and transportation relative to their value, means that in a period of rising prices one can retain almost all of one’s purchasing power simply by owning gold or silver. All that is necessary is that their price rise merely to the same extent as the average of prices. Although, if this happens, one will suffer the modest loss of having to pay storage costs, this is far less of a loss than tends to be suffered in connection with the customary forms of saving and investment in such conditions.

The customary forms of investment lose because of

all of the ways in which inflation undermines capital formation. The customary forms of investment can be compared to the purchase of equipment which inflation will cause to end up as mere heaps of scrap iron. At some point, of course, as the result of inflation, even the price of scrap iron in the future will be higher than the price of the equipment today. But when it is, the prices of everything else will obviously have increased by much more. Thus the purchaser of ordinary business assets, or any form of claim to such assets, ends up, on average, a major loser. He starts with the price of equipment, and ends with the price of scrap iron, while the prices of the things he wants to buy advance more or less in line with the price of replacement equipment. The example may be somewhat exaggerated, but it is correct in describing the nature of what happens. For such is the result of the taxation of funds required for replacement, of the prosperity delusion, of widespread malinvestment, of the loss of safety of all the traditional, conservative forms of investment, and of the withdrawal-of-wealth effect.

Since the ownership of gold and silver entail a much lesser loss, their ownership becomes relatively favored, and thus, for a considerable time, their price can actually rise by more than the average of prices, as larger and larger numbers of people shift portions of their savings into them. In effect, because of their special suitability for serving as inflation hedges, the phenomenon of substantial inflation creates a new and additional demand for them, on the basis of which their value is substantially increased. (By the same token, of course, the moment inflation comes to be perceived as less of a threat, the demand for gold and silver as inflation hedges diminishes, and thus their price declines relative to the average of prices.)

It follows that if not prevented from doing so by government interference, the market itself would take all of the necessary precautions against the destruction of money, by preparing the ground for the reemergence of gold and silver as money. For the remonetization of the precious metals would readily follow from their being owned and sought as a store of value by a substantial portion of the population.¹⁰⁶

A Proper Gold Policy for the Government

The process of the spontaneous remonetization of gold and silver would be enormously accelerated in the absence of various government restrictions. It goes without saying that buyers and sellers of gold and silver should not be subjected to any invasion of their privacy, such as having to report their purchases and sales to the government. The purchase and sale of gold and silver should also not be subject to taxation of any kind. The ability of people to protect themselves by means of the

ownership of gold and silver from the loss of purchasing power that inflation causes should not in any way be reduced by taxes that must be paid merely because the price of gold or silver rises. In the absence of such taxes and with the ability freely to buy and sell, the ownership of gold and silver would increase much more rapidly.

In addition, the government should do absolutely nothing to prevent the importation of gold from abroad. The present quantity of gold that is owned by American citizens and by their government is almost certainly substantially below the quantity that they would want to own under a gold monetary system. The present real value of an ounce of gold is likewise far below what it would be under such a system. The ability freely to import gold now means the ability to acquire it while it is still relatively cheap.

An integral part of the process of spontaneous remonetization would be the enforcement of contracts calling for payment in gold or silver, along with the freedom of such contracts from taxation on the mere rise in price of gold or silver. Thus, for example, the law should enforce such contracts as the loan of 100 ounces of gold today in exchange for the repayment of 105 ounces of gold a year from now. At the same time, it should regard as the taxable income in connection with such a contract merely the 5 ounces of gold interest, not any increase in the paper money price of the 105 ounces of gold principal and interest.

If such a policy existed, any substantial perception of inflation as a serious problem would be accompanied by the emergence of contracts payable in gold or silver. Gold and silver capital and credit markets would develop. At the same time that people became unwilling any longer to lend paper money on a long-term basis, because they came to recognize that they must lose by doing so, they would become eager to lend gold. Provided the repayment of the principal could be assured, the receipt of any gold interest whatever would represent an improvement over the mere holding of the gold. Thus, for example, a recurrence of the conditions of the late 1970s and early 1980s, in which long-term fixed-rate mortgages were about to disappear, would mean the disappearance of such mortgages only in terms of paper money. Long-term fixed-rate mortgages payable in paper money would be replaced with long-term fixed-rate mortgages payable in gold.

The spread of contracts payable in gold or silver would powerfully promote the remonetization of these metals, because whoever came to owe gold or silver would be a willing seller for gold or silver. The existence of a growing number of sellers seeking gold or silver as a means of meeting their contractual obligations would widen the exchangeability of gold and silver beyond

what it would be on the basis of the demand merely for holdings of gold and silver. The exchangeability of gold and silver for all kinds of ordinary goods and services would soon become great enough to make everyone willing to accept them, because all would have the confident expectation of finding others willing to take them in turn. At that point, gold and silver would once again be money.

An essential aspect of gold and silver achieving a monetary role is the abolition of all restrictions on the ability of merchants to practice discrimination between units of precious-metal money and units of paper money bearing the same face value. This means, for example, that merchants should have full freedom to discriminate between an old \$20 gold piece (or a contemporary re-strike of such a gold piece) and a \$20 bill. They should be able to accept the \$20 gold piece as the equivalent of however many hundreds or thousands of dollars of paper money as its market value dictates. In exactly the same way, they should be free to discriminate between pre-1965 silver coins and contemporary coins and currency of the same face value. They should be free to accept a roll of pre-1965 silver quarters with a face value of \$10 as the equivalent of however many present-day \$10 bills as its market value dictates. By the same token, they should have the freedom to take gold and silver coins of a given face value as their standard of the *meaning* of the number of dollars of that face value, and to declare paper money of the same face value to be acceptable only at a discount, that is, as worth only so many cents on the dollar of precious-metal money. For example, if a \$20 gold piece has a market value of \$500, merchants should be able to declare that the \$20 gold piece is what they mean by \$20 and that they accept paper dollars at the rate of only 4 gold cents on the dollar.

The existence of gold and silver moneys operating alongside of a fiat paper money, and in free competition with the fiat money, would greatly accelerate the doom of the fiat money, unless the latter were made redeemable on demand in gold or silver at a fixed, known rate, which there was no expectation that the government would change. This is because in these circumstances, people would have an alternative to the depreciating fiat money. In the face of this alternative, the demand for paper money would quickly evaporate as people shifted their allegiance to the vastly superior gold and silver moneys, which retained or increased their buying power as the fiat money declined in buying power. They would want their principal and interest, their pensions, life insurance, rental agreements, and all other contracts payable in the gold and silver moneys they could trust, and not in the depreciating fiat money. To remain in existence at all, the fiat money would have to be made into a gold-standard

money—which is what it means to be redeemable on demand at a fixed, unchanging rate. These results would follow from people's direct perception, in their day-to-day transactions, of the superiority of the precious metals in retaining their buying power. They would see, for example, how a \$20 gold piece came to be equivalent to hundreds or thousands of dollars of paper money, and how a silver dime or quarter came to be equivalent to larger and larger multiples of fiat money. In other words, they would directly perceive the fact that the problem of inflation lay in the paper money, which they would then turn away from.¹⁰⁷

It follows from the above description of things that gold is the money of a free market and that fiat money can be maintained in existence only by the forcible suppression of the competition of gold. It should also be clear that the requirement that paper money be redeemable in gold at a fixed, known rate is not any form of price control, as some economists with inadequate knowledge of the subject maintain, but an indispensable means of keeping paper money in existence when it must compete in a free market. In a free market, there would simply be no demand for an irredeemable paper money, which in the nature of things is capable of being inflated without limit.

The government, which has done almost everything in its power to destroy the use of gold as money, could take a number of important and perfectly legitimate measures to promote the remonetization of gold.¹⁰⁸ For a nominal fee, and for a limited number of years, it could allow private minters, who would manufacture new gold or silver coins, to use the seal of the United States on one side of their coins, until such time as the market became familiar with their respective trademarks. It could and should also begin to collect some tax revenues in gold and silver, such as the proceeds of the tariff, and perhaps some excise taxes. This measure would immediately sharply increase the demand for gold and its value. It would immediately make payment in gold acceptable to whoever had to pay such taxes. It would be a clear indication to everyone of the course of things to come. It would also provide the government with a secure source of revenue that would be more than sufficient to maintain its essential, non-welfare-state, peacetime functions. Thus, the continued existence of the government itself would be substantially secured against the possibility of a currency collapse.

The collection of these taxes in gold would promote the highly desirable objective of the monetary demand for gold increasing as far as possible *in advance* of major financial obligations coming to be expressed in gold. This is necessary in order for borrowers of gold not to find that it is vastly more difficult to acquire it at the time

of repayment than at the time they borrowed it. A gradually increasing volume of contracts payable in gold would present no major problem, because the upward pressure on the real value of gold created by a growing demand for it to make principal and interest payments, and to buy from those seeking gold for such purposes, would at the same time elevate its value for all the new contracts being written. However, a measure such as the collection of the tariff and various excise taxes in gold, which could be phased in over a period of two or three years, would help to increase the monetary demand for gold all the more quickly, and thus correspondingly diminish any possible burden imposed by a growing monetary demand concentrated more heavily in the future. It would make gold a safe medium that much sooner in which to contract a large volume of financial obligations.

The same objective would be promoted by the government's adopting a policy of auctioning off, for gold, various assets it presently owns and should not own. These include its vast landholdings in the Western states and Alaska, the postal system, Amtrak, Conrail, the Tennessee Valley Authority and other facilities for producing electric power, and the interstate highway system. The gold taken in from the sale of such assets might be used to increase the gold stock available for the future redemption of the paper currency and outstanding fiduciary media, or, if it should prove excessive for that purpose, for the redemption of a portion of the national debt.

A further perfectly legitimate measure that the government might adopt in connection with promoting the remonetization of gold would be the enactment of a creditors' protection bill, which would make some modest portion of existing contracts, such as 5 percent of the sums involved, payable in gold, at the price of gold prevailing at the time of the bill's enactment. Such payment would be at the option of the creditor, who would elect it only in the event that the paper money due him fell below the price of the gold in question. As well as encouraging the use of gold, this measure would ensure that inflation would not be able to wipe out the wealth of creditors entirely. Depending on the extent to which the price of gold later came to rise relative to the average of prices, the measure could succeed in preserving a significant portion of the purchasing power of the contractual sums to which it applied, irrespective of the degree of inflation. For example, an outstanding contract calling for the payment of \$1 million would be construed as requiring the payment of a quantity of gold presently equal to \$50,000. If the prevailing price of gold were \$500 per ounce, this would mean that such a contract required the payment of 100 ounces of gold at the option of the creditor. This would guarantee that no matter how

great inflation became, the creditor would receive at least some significant payment in real terms. Indeed, the worse inflation became, the more would the rise in the price of gold tend to outstrip the rise in the average of prices. Thus, if, as is easily conceivable, in the course of a major inflation the price of gold rose seven or eight times as much as the average of prices, the creditor would end up at least receiving 35 or 40 percent of the real payment due him.

Neither the government nor anyone else would have to take payment in gold or silver in actual coin or bullion. Payment could be made with gold-denominated banknotes or checks. But the government could legitimately require, and indeed should in fact require, at least for the length of the period of transition and for some time beyond, that all banknotes and checks payable in gold or silver, be covered by a 100-percent-gold-or-silver reserve, as the case may be. The government itself should never accept anything but either coin or bullion or notes or deposits 100 percent backed by coin or bullion. If it accepts any form of fractional-reserve money, it places itself in a position in which it implicitly grants credit, which is not part of its proper function and which it has no right to do. The implicit granting of credit is entailed to the extent that the claim one accepts or holds is backed by debt rather than by actual money. Until one receives actual money or a fully backed receipt for actual money, one has not yet been paid, but is granting credit.

2. The Case For a 100-Percent-Reserve Gold Standard

The establishment of a monetary system that was based not only on the widespread use of gold and silver coin, but also on the principal of a 100-percent-gold-or-silver reserve against banknotes and checking deposits, would mean security not only against a possible currency collapse but against every aspect of inflation. It would be a monetary system that would be both inflation proof and deflation/depression proof.

Under a 100-percent-reserve gold standard, every unit of money *is* a physical unit of gold. The paper currency and checking deposits are merely money substitutes, i.e., transferable claims to actual money, which is gold. For example, if the dollar were defined as one-twentieth of an ounce of pure gold (which it was, roughly speaking, for most of our history), then there could be only twenty times as many dollars in the United States as there were physical ounces of gold. If, say, there were \$20 billion of paper currency and checking deposits outstanding, there would have to be one billion ounces of gold standing behind them.

This example, of course, is purely for purposes of illustration. I certainly do not advocate the definition of

the dollar as one-twentieth of an ounce of gold today. Given all the inflation in the United States in this century, one *three-thousandth* of an ounce would be a far more reasonable definition, and, as time goes on and still more inflation ensues, the amount of gold in terms of which the dollar was defined would have to be still less.¹⁰⁹ In fact, after a period of conversion, I would advocate abandoning the very name “dollar” and defining the monetary unit simply as a weight of gold, such as the gold ounce or the gold gram. We would then speak of “ounces” or “grams” of gold as the British, French, and Italians once did of pounds, livre, and lire of silver. (All of these units originally denoted a troy pound of silver.)¹¹⁰

A 100-percent-reserve gold standard would obviously provide a guarantee against inflation. Gold is rare in nature and extremely costly to mine in anything but relatively small amounts. A gold money would increase in quantity from year to year probably by only about two or three percent, if that. Between a modest growth in population and thus in the supply of labor, and a rise in the output per worker based on technological progress and capital accumulation, it is likely that in most years the increase in the overall supply of goods would outstrip the increase in the supply of gold. The result would be that prices would show a tendency to fall from year to year. As I previously pointed out, this is actually what happened in the nineteenth century, in the generation preceding the discovery of the California gold fields, and again, in the generation from 1873 to 1896.

Falling Prices Under the 100-Percent-Reserve Gold Standard Would Not Be Deflationary

Paradoxically, it is precisely the gold standard’s success in preventing inflationary increases in the money supply that is the source of much of the opposition to it. People believe that the fall in prices that would occur under the gold standard would represent deflation. And, as a result, they believe that the economic system would languish in a state of more or less permanent depression.

Amazingly, even most of the supporters of the gold standard appear to believe this in some form. They advocate a *fractional*-reserve gold standard in the belief that it is necessary to make the money supply grow more rapidly than the increase in gold taken by itself. In effect, they want each additional ounce of gold to make possible the creation of money substitutes representing claims to two, five, ten, or more ounces of gold. They apparently do not realize that if they were right, the implication of their position would ultimately be no gold standard at all. For if it in fact were necessary for the quantity of money to grow more rapidly than the supply of gold, then each year the supply of gold would represent an ever smaller fraction of the supply of money. Eventually the fraction

would approach zero. If, on the other hand, gold is always to constitute the same fraction of the money supply, then it is impossible for the money supply to grow more rapidly than gold, and one may as well have a 100-percent-gold reserve. Indeed, the rate of increase in the supply of gold itself is likely to be greater under a 100-percent-reserve system than under any fractional-reserve system in which the fraction of gold is fixed. This is because the real value of gold is greatest under a 100-percent-reserve system and therefore the inducement to the increase in its supply the strongest.

Of course, it should be obvious on the basis of previous discussion, that the fall in prices that would occur under the 100-percent-reserve gold standard would not at all represent deflation.¹¹¹ In the nature of the case, such a fall in prices would be the result of an increase in production, not a decrease in spending. Because of this, it would not be accompanied by any of the essential symptoms of deflation: namely, a greater difficulty of repaying debts and a wiping out of the rate of profit on capital invested.

Under the 100-percent-reserve gold standard, total sales revenues in the economic system would in fact modestly increase from year to year, in accordance with the modest increase in the gold money supply and the volume of spending in terms of gold. The average business firm would thus find that its sales revenues modestly increased from year to year. The fact that the average business firm might have to sell at somewhat lower prices from year to year would not in any way imply a reduction in its sales revenues. On the contrary, it would have a supply of goods to sell that was larger by more than corresponded to the fall in prices, and was so to a significant degree. The fall in prices, it cannot be stressed too strongly, would be the result not of a fall in spending, not even of an increase in supply in the face of a given volume of spending, but of an increase in supply which outstripped an *increase* in spending. In such circumstances, a greater increase in the supply of goods than corresponds to the fall in prices exists to precisely the same extent as the increase in the volume of spending in terms of gold.

The context of why prices fall under the 100-percent-reserve gold standard must be kept in mind: it is because while spending rises 2 or 3 percent a year, in accordance with the increase in the gold supply, production rises 4, 5, or 6 percent a year. This kind of drop in prices is not accompanied by declining sales revenues, but by modestly rising sales revenues. The rise in sales revenues is the corollary of the rise in spending. Any business firm that increases its production in accordance with the economy-wide average increase has no greater difficulty in earning a dollar of sales revenue at the lower prices that

prevail later on than it had at the higher prices that prevailed earlier. In fact, it necessarily has a somewhat *easier* time earning a dollar of sales revenues, for the supply of goods it is able to produce and sell goes up by more than the price of its goods must fall. Because it is no harder to earn a dollar later on than it was earlier, but easier, there is not only no greater difficulty of repaying debts, as there is under deflation, but a lesser difficulty. Thus, this symptom of deflation is most decidedly not present.

Nor is the fall in prices under the 100-percent-reserve gold standard accompanied by any wiping out of the average rate of profit in the economic system, which is the other leading symptom of deflation. On the contrary, the increase in the quantity of money and volume of spending that takes place under the 100-percent-reserve gold standard represents a corresponding addition to the nominal rate of profit. To whatever extent the increase in production and supply outstrips the increase in the quantity of money and volume of spending, the resulting fall in prices is merely the measure by which the addition to the real rate of profit exceeds the addition to the nominal rate of profit.¹¹²

Thus, falling prices under a 100-percent-reserve gold standard simply do not represent deflation. They do not make it more difficult for the average debtor to repay his debts and they do not reduce the average rate of profit.

It is a very different story, however, when prices fall not as they do under the 100-percent-reserve gold standard, because of more production, but because of less spending in the economy. Then the fall in prices is accompanied by a decline in the sales revenues of the average seller. Then it *is* more difficult for the average debtor to repay his debts, because whether he has more goods to sell or less goods to sell, there simply isn't as much money to be taken in by him. And because sales revenues fall, the average rate of profit falls, corresponding to the lag between a fall in productive expenditure and a fall in depreciation cost and cost of goods sold.¹¹³

The fact is that deflation is not a matter of falling prices, but of a contraction in the volume of spending in the economy. This is what produces the essential symptoms of deflation: the general inability to repay debts and the wiping out of business profitability. If this point is kept in mind, then it becomes clear that a 100-percent-reserve gold standard not only would not cause deflation, but would actually be the best possible protection *against* deflation.

The 100-Percent-Reserve Gold Standard as the Guarantee Against Deflation

There are two basic reasons why the 100-percent-reserve gold standard would be a guarantee against defla-

tion. First, under a 100-percent-reserve gold standard, nothing could happen that would suddenly reduce the quantity of money in the economic system. Once gold money comes into existence, it *stays* in existence. It is not wiped out by the failure of debtors, as are fiduciary media. Second, nothing could happen that would suddenly increase the need or desire of people to hold money rather than spend it, because none of the artificial inducements to a lower demand for money for holding would exist that set the stage for such an increase. It must be recalled that what creates the potential for a sudden increase in the need and desire to hold money is that first, people are misled into experiencing an artificial decrease in their need and desire to hold money. All the inducements that mislead them into this decrease are caused by the prior undue increase in the quantity of money, especially in the form of credit expansion.¹¹⁴ A 100-percent-reserve gold standard would thus be a system in which the quantity of money would not decrease and the demand for money for holding would not suddenly increase. As a result, it would be a system in which total spending in the economy would virtually never contract. Thus, as stated, it would be a system that was deflation proof as well as inflation proof.

Under the 100-percent-reserve gold standard, the desire to hold money would be substantially greater than it is today and also greater than it would be under a fractional-reserve gold standard. Money would be something for which people would have great respect and would want to own in abundance. And they would succeed in owning it in abundance. However paradoxical it may seem, the 100-percent-reserve gold standard would be a system of *enormous financial liquidity*. It would be a system in which the quantity of money measured in terms of its absolute buying power and relative to such things as current liabilities, would be far greater than under any other system. It is precisely for this reason that there would be no basis for any sudden increase in the need or desire of people to own money. They would *already own* all the money they needed to.

This point may be difficult to grasp. The prevailing view is that anyone who wants to hold money is practically a public enemy, and that financial virtue, at least from a social point of view, consists of everyone spending his every dollar as rapidly as possible.

However, a different conclusion emerges if one considers a 100-percent-reserve gold standard and thinks through the effects of people wanting to hold money more tightly. Thus, let us imagine that there are only a billion ounces of gold in the world and that initially people are spending this gold fast enough to generate a five billion gold-ounce world “gross product”—in other words, the so-called velocity of circulation of money, or

turnover, is five. Now people decide they want to hold the gold much more tightly. The velocity of circulation and the world “gross product” plunge from five and five billion respectively to, say, two and two billion respectively.

At a sufficiently lower level of wages and prices, the two billion ounce world “gross product” can buy all that the five billion ounce world “gross product” bought. The only difference is that the buying power of the one billion ounce money supply will be much larger and that the money supply will stand in a much higher ratio to magnitudes such as total current liabilities and total accounts receivable. These magnitudes will fall in accordance with the fall in spending, and then stay down as wage rates and prices fall to make possible a recovery in employment and production. In other words, the result will be that the system will have *more money in terms of actual buying power and will thus be correspondingly more liquid*.¹¹⁵

Under a 100-percent-reserve gold standard, a sufficiently high degree of liquidity would once and for all long ago have been achieved and no further need would exist suddenly to increase it. The system would operate permanently in accordance with the most conservative rules of financial management and never be placed in the position of having to experience a financial contraction. As a result, the kind of example just given would not actually occur under the 100-percent-reserve gold standard. It is descriptive, however, of what happens when the artificial stimulus given to spending by inflation comes to an end.

On the basis of all these reasons, it should be clear why the 100-percent-reserve gold standard would be the solution to the boom-bust business cycle, as well as the solution to the problem of inflation.

Further Virtues of the 100-Percent-Reserve Gold Standard

Among the other major virtues of the 100-percent-reserve gold standard is that, in common with the more serious forms of a fractional-reserve gold standard, it would make possible a unified world monetary system with all its attendant advantages to international investment and the international division of labor. International investment need no longer be subject to the risk of depreciation in the foreign currency in which the investment was made. If the foreign currency is also a weight of gold, then for all practical purposes it is the same as the domestic currency.

Even more important, and with firmer guarantees than any form of fractional-reserve gold standard can provide (because of the total ban it establishes on the creation of new and additional money by the government and the

banking system), the 100-percent-reserve gold standard would compel governments to operate with balanced budgets, since they would have to turn to their citizens for all the money they spent. Governments would simply no longer have the power to spend more than the taxes they collected. They could absolutely no longer finance their deficits by creating money. Nor could they hope to finance them for very long by borrowing gold, since a policy of borrowing gold would plunge a government into bankruptcy and would soon have to be abandoned, or, more likely, avoided in the first place. The consequent absolute physical need to balance the budget would in turn, of course, greatly reduce the popularity of all government spending programs, because all of them would be perceived in inseparable connection with the taxes that would be required to pay for them. This in turn would mean fewer and smaller such programs; hence, a smaller, less expensive, and less destructive government. The same principle would apply to wars, as well. Instead of being perceived as periods of prosperity, the higher taxes required to pay for them would make the public correctly identify them as periods of impoverishment. As a result wars would be less frequent and of shorter duration.

In addition, a 100-percent-reserve gold standard would provide an environment enormously conducive to saving, investment, and capital accumulation. The arbitrary redistribution of wealth and income caused by inflation would end; the future purchasing power of money would be assured; the general profitability of investment would be assured (something which fractional-reserve gold standards with their attendant depressions cannot do); and neither profits nor interest would be artificially inflated, as occurs today, and then taxed and consumed as though they were genuine gains rather than being necessary merely for the replacement of assets at higher prices. On the contrary, under the 100-percent-reserve gold standard, far more than under any form of fractional-reserve gold standard (because of the more limited potential for increase in the quantity of money), a substantial portion of profit and interest income in real terms would automatically escape all taxation—namely, all that portion which took the form of a greater buying power of the original capital funds resulting from lower replacement prices of assets. Furthermore, unlike under the fractional-reserve gold standard and its accompanying credit expansions, there would be no malinvestment or withdrawal-of-wealth effects to hamper capital formation.

The Moral Virtue of the 100-Percent-Reserve Gold Standard

What underlies the practical advantages of the 100-percent-reserve gold standard over any form of frac-

tional-reserve system is its moral superiority. It operates consistently with the law of the excluded middle and does not attempt to cheat reality by getting away with a contradiction. It recognizes that lending money precludes retaining that money in one's possession, and that retaining money in one's possession precludes lending it. The 100-percent-reserve system follows the principle that either one lends money or one retains the money, but not both together, with one and the same sum of money. In contrast, a fractional-reserve system applied to checking deposits or banknotes is a deliberate attempt to cheat reality. It is the attempt to have one's money and lend it too. It is a system fully as dishonest as all other recurring efforts that take place in one form or another in attempts "to have one's cake and eat it too."

Just as such attempts typically entail taking away someone else's cake, fractional-reserve banking applied to checking deposits or banknotes entails some parties gaining credit at the expense of other parties, and others unexpectedly being placed in need of credit. Again and again it results in financial contractions, depressions, and deflation, accompanied by widespread bank failures, which last represents the cheating coming home to roost. Again and again, individuals who believed they owned money, who would never have dreamed of lending out the money they needed to hold to make purchases and pay bills, and thus of lending to the point of their own insolvency, wake up to learn that the checking deposits or banknotes they hold represent loans that have become uncollectable.

Imposition of the 100-percent-reserve principle in connection with checking deposits and banknotes is the imposition of financial honesty. It would require nothing more than that banks ask their customers whether in making a deposit or buying banknotes their intention was to lend money to the bank or to keep their money at the bank. In the first case, the bank's customers would receive a credit to a savings account or certificates of deposit, neither of which they could spend until such time as they withdrew the funds they had lent, which would entail equivalently reducing their savings account or redeeming their certificates of deposit. During the interval the bank, for its part, could lend the customers' money out, as it thought best. In the second case, the customers would receive either a credit to their checking account or banknotes, both of which they could spend as they wished. But so long as the customers held their funds in the form of checking accounts or banknotes, the bank could not lend or spend the proceeds its customers had entrusted to it. That money would be the customers' money, which they were not lending to the bank but merely keeping at the bank.

It follows from this discussion that it is mistaken to

believe that the imposition by law of 100-percent-reserve banking in connection with checking deposits and banknotes would constitute government interference. It would constitute nothing more than the just exercise of the government's power to combat fraud—the fraud of having one's funds lent out despite the bank's deliberate creation of the impression that in making a checking deposit or purchasing banknotes one fully retained the possession of one's funds.

Shysterism in any form is always slippery. Thus if it occurs to anyone to argue that the banks' customers are not victims of fraud because they clearly know and understand that their funds are being lent out, then the answer is that in that case they would be parties to fraud. Their fraud would be the attempt to make payment to others not with money or reliable warehouse receipts for money, but with claims to debt. They would be engaged in the willful contradiction and deception of claiming to pay someone when in fact imposing on him the position of being a grantor of credit.

It should be understood that everything I have said in connection with the subject of the fraud entailed in fractional-reserve banking applies to a context in which the establishment of a 100-percent-reserve gold standard would be a real possibility. It is pointless to accuse either banks or their customers of any kind of fraud in connection with fractional-reserve banking in a context such as that of the present, in which the overwhelmingly greater fraud exists of the government's creation of a monetary standard that is utterly nonobjective and arbitrary, namely, the fiat-paper standard.

Supporters of fiduciary media and credit expansion like to argue that their effect is an increase in the volume of capital and credit that exists in the economic system. This is true, of course, only in terms of a monetary unit that is of lesser value because of credit expansion and the creation of fiduciary media. I have already shown at length how credit expansion and fiduciary media undermine capital accumulation in real terms. It is worth pointing out, however, that even if the advocates of credit expansion and the creation of fiduciary media were correct, any loss of capital and credit as might be attributable to their elimination could far more than be made up for by reduction in the national debt. As of the end of 1993, the cumulative total of loans and investments acquired by the banking system in connection with the creation of fiduciary media was approximately \$738 billion.¹¹⁶ At the same time, the national debt, which is the measure of the cumulative siphoning off of savings and capital into the consumption of the government, stood at almost \$4.6 trillion, i.e., was more than six times as large.¹¹⁷ Thus, even if fractional-reserve banking and

the issuance of fiduciary media, instead of undermining capital formation as they actually do, somehow made a contribution to capital and credit that could be measured as equal to the amount of debt held by the banking system as the result of the issuance of fiduciary media, the loss of such contribution could easily be far more than made good by the reduction of the national debt.

It is simply absurd for anyone to engage in sophistic speculations about how to use methods of cheating as sources of additional capital, when overwhelmingly more capital could be made available by the perfectly honest method of reducing the national debt and ultimately eliminating it. Unfortunately, there are people who like to speculate in this way because of the perverse attraction cheating holds for them.

The Monetary Role of Silver

The existence of a 100-percent-reserve gold standard would imply a major monetary role for silver. This is because the extremely high real value that would then exist for even the smallest practical-sized gold coin would make it impossible for gold coins to effectuate most retail purchases. Even at the relatively low prices of gold that have prevailed in the last decade, the smallest practical-sized gold coin has a buying power that is too high for many retail transactions. For example, at a price of gold of \$400 per ounce, the smallest practical-sized gold coin has a buying power of approximately \$20. (This is a coin weighing slightly less than a twentieth of an ounce of gold, which was the size of the smallest old U.S. gold coin, namely, the one-dollar gold piece.) Under a full, 100-percent-reserve gold monetary system, the buying power of an ounce of gold would be far greater, which would rule out the use of gold coin in the great majority of retail transactions.

The fact that the value of gold would be too great for most retail transactions implies that if the monetary system is to make extensive use of precious-metal coins, a major monetary role must exist for silver, which would be in use alongside gold, constituting a second, independent, parallel standard.¹¹⁸ Silver was the market's answer historically to the problems posed by the very high real value of even the smallest gold coins. For many centuries it had a value of approximately one-fifteenth that of gold.

The widespread use of silver coins, rather than gold-backed banknotes or checks for most day-to-day retail transactions, is implied by the fact that under a 100-percent-reserve system, there is a substantial cost in using banknotes and checks. This is because the banks must charge fees high enough to cover the cost of maintaining and safeguarding the reserves, as well as doing whatever else is necessary in providing the services of banknotes and checking deposits. Thus the use of coins is made

preferable in most such cases, but gold coins are too valuable for most day-to-day retail transactions, which leaves silver coins.

Under a 100-percent-reserve gold standard, the monetary role of silver might be so great that silver coin and bullion would constitute as much as a third of the overall supply of money. This estimate is consistent with the fact that today, paper currency in denominations of \$100 and less, together with subsidiary coin, constitutes on the order of a third of the overall quantity of money, while checking balances constitute the rest. Under a 100-percent-reserve gold standard, silver coins would take the place of most of today's paper currency and would have a buying power ranging from today's \$10 bills up through today's \$100 bills.

This estimate of the buying power of silver coins is consistent with the assumption of an ounce of gold having a buying power of approximately \$3,000 of today's money, and an ounce of silver coming once again to have a buying power of one-fifteenth as much, that is, of approximately \$200. The assumption of a buying power of \$3,000 for an ounce of gold follows from dividing the present government-held gold stock of approximately 260 million ounces into two-thirds of \$1,150 billion, which is the approximate present money supply of the United States. It is divided into two-thirds of the money supply on the assumption that silver would constitute the other one-third of the money supply. On these assumptions, a silver coin the size of the pre-1965 dime, which contained about .07 ounces of silver, would have a buying power of about \$14, while the larger silver coins had proportionately greater buying power. (Recognition that the precious metals could attain such buying power helps to explain the very low prices that prevailed in previous centuries. For example, the fact that in the mid-nineteenth century one could buy a steak in a restaurant for 10¢ or a pot of coffee for 2¢, is consistent with such high real values of the precious metals.)

With such great buying power on the part of the precious metals, even the smallest practical-sized silver coin would have too great a purchasing power for small retail transactions, namely, those of approximately \$10 or less in terms of today's money. Historically, this is what necessitated the existence of a subsidiary token coinage ranging from 5 cent pieces on down to half-cent pieces. A lowly half-cent piece had a buying power comparable to 70 cents of today's money.

The case of subsidiary, token coinage represents the one proper area for the issuance of fiduciary media. On the one hand, the existence of such coinage is necessary to facilitate transactions that could not otherwise readily be facilitated. As such, it does not displace gold or silver

but supplements them. On the other hand, there is no convenient way to make the issuance of such coinage profitable except by the earning of interest on the lending out of a substantial portion of any standard money received by the issuer in exchange for the token coins. To require a 100 percent reserve in this case would be to require that the token coins circulate at a premium over the gold or silver for which they were redeemable, a premium equal to the cost of providing them and of maintaining the gold or silver reserves. If the same token coins were to remain in circulation for many years, their redemption value in gold or silver would have to be progressively reduced in order to cover the on-going cost of maintaining the gold or silver reserves. Such difficulties are eliminated by providing for the costs out of interest earnings on the lending out of much of the standard money the issuer receives in exchange for the token money.

Because such coinage supplements the precious metals rather than displaces them, its issuance does not diminish their value, as does the issuance of fiduciary media in normal circumstances. On the contrary, to whatever extent the precious metals serve as a reserve against the token coinage, their value is somewhat enhanced, because now, indirectly, in the form of a reserve, they enter to an important extent into the token coinage, which they could not do directly, as circulating coin. Moreover, unlike the case of fiduciary media in normal circumstances, there is no danger of credit expansion from any excess issuance of token coinage. Whoever would seek to expand credit by manufacturing and lending out additional rolls of pennies and nickels would find that virtually all of them immediately came back to him in exchange for gold or silver, because there would be no way to induce people suddenly to increase the proportion of their money that they wished to hold in the form of minor coins. If the issuer proved unable to redeem his coins in such a case, it is unlikely that anyone's loss would be very significant if he had behaved reasonably and had accepted no more than modest amounts of such additional coins. The largest losers would probably be the customers who had borrowed the coins and who had not been able to pass all of them before they lost their redeemability.

3. The 100-Percent-Reserve Gold Standard as the Means of Ending Inflation Without a Depression

The remonetization of gold and silver on a 100-percent-reserve basis holds out the prospect of ending inflation once and for all and of doing so without causing a financial contraction or depression.¹¹⁹ In order to explain how, it is necessary to begin with the following facts.

As of December 1993, the money supply of the United States was approximately \$1,100 billion, and the so-called gross domestic product (GDP) of the United States was running at an annual rate of about \$6,400 billion.¹²⁰ With an \$1,100 billion money supply and a \$6,400 billion GDP, the implied income velocity of money was somewhat less than 6.

If all that were done at this point was to stop all further inflation of fiat money, make it redeemable in gold, and permanently limit the rate of increase in the quantity of money to the rate of increase in the supply of gold, the sharply higher demand for money that would result might well drive velocity down to 4 or even 3 (its approximate level through most of the 1930s) and thus initially reduce nominal GDP to close to \$4,000 billion or even \$3,000 billion. In the process, of course, there would be an enormous wave of bankruptcies and bank failures, which would have the potential for wiping out the greater part of the money supply and thus reducing nominal GDP and total spending all that much further. Indeed, starting with the present velocity of almost 6, it may well be the case that the deflationary potential which exists today is substantially greater than the deflation that occurred between the years 1929 and 1933, which started in the face of a velocity of circulation in the neighborhood of 4.

All this, of course, indicates the enormous difficulties in the way of ending inflation under present monetary conditions. But not to end inflation means the continuation of all of its destructive consequences. These, it should be recalled, include: (1) perversion of the institutions of representative government by removing the financial dependence of the government on the citizenry and making the citizens appear to be dependent on the government, (2) the consequent growth in the size of government, (3) the redistribution of wealth and income, which further contributes to the growth in the size of government through its creation of impoverishment, (4) the undermining of saving and capital accumulation, which has the same effect as the previous point, (5) increased hostility to profits and interest accompanied by the threat of price-and-wage controls and thus the chaos and tyranny of socialism, and, finally, (6) the likelihood of a renewed acceleration of inflation. This last not only would make all of the destructive consequences either that much worse or more likely, but would also open up the possibility of the destruction of credit and even of money itself. In its potential for bringing about the destruction both of the price system and of money (the former through leading to price controls and socialism), inflation, as we have seen, represents a long-term threat to the continued existence of modern material civilization.¹²¹

This terrible dilemma, of having to choose between a

catastrophic depression, on the one side, and the continual wearing down and ultimate destruction of modern material civilization, on the other, is what adoption of a 100-percent-reserve gold standard is capable of avoiding. It is, as I say, capable of ending inflation once and for all without precipitating a financial contraction or depression.

To understand just how this is possible, let us imagine that our present money supply of approximately \$1,100 billion consisted of nothing but gold, and that this had been brought about by the government taking its gold holding of approximately 260 million ounces and pricing it high enough to make it equal to \$1,100 billion. A price of something more than \$4,000 per ounce would accomplish this.¹²²

Imagine that the government physically distributed this gold to the people: It called in all the paper currency and gave out very small gold coins in exchange; and it turned the remainder of its gold over to the banks, to place their checking deposits on a 100-percent-gold-reserve basis.¹²³ For the sake of maximum simplicity, we can think of the money supply as now consisting of 260 million one-ounce gold coins. (Obviously, much smaller denominations would be necessary, but let's think of it this way.) Imagine that on one side of each of these coins it said "1 ounce of gold," and on the other side "\$4,000." In the same way, imagine that all checking deposits were denominated both in terms of ounces of gold and in terms of dollars. The money supply could then be looked at as being either 260 million gold ounces or \$1,100 billion. People would certainly want to hold this gold money supply very tightly, because the possibility of inflation would now have been definitively ended, since the money supply would actually be gold and thus there would physically be just no way for the government to increase it. People would hold the money not as dollars, but as pieces of gold.

Let us imagine that people wanted to hold this money supply so tightly that its velocity of circulation would be only 3. Thus, in terms of gold, GDP would be three times the 260 million ounces of gold, or 780 million ounces. In terms of dollars, however, the effect would be that GDP would plunge to little more than \$3,000 billion (i.e., to \$4,000 times 780 million), which is the very situation we wanted to avoid.

But now let's make a change in our example. While the gold money supply remains at 260 million ounces and its velocity remains at 3—because it is gold that people are holding—let us see what happens if we assume a higher price of gold imprinted on each coin. Imagine that on the dollar side of each of the one-ounce gold coins that constitute the money supply, it said not "\$4,000," but "\$8,000." Observe. The gold money supply remains 260

million ounces and the gold GDP remains 780 million ounces. But the dollar money supply now becomes \$2,200 billion—twice as large. And the dollar GDP now becomes more than \$6,000 billion—also twice as large. This \$6,000 billion-plus GDP, of course, is the original size of GDP.

Now I am not in fact advocating a gold price nearly as high as \$8,000 in today's circumstances—for reasons that I will explain shortly. I used it just to illustrate an important point. And that is, that in principle it would be possible to stop inflation cold with a 100-percent-gold money, and simultaneously to offset the resulting fall in the velocity of circulation of money. This last would be accomplished by making the gold supply equal to enough dollars to leave spending in terms of dollars unchanged at the lower velocity. In other words, it is possible to stop inflation cold, and yet avoid the contraction in dollars spent that would otherwise result from a greater need and desire to hold money, simply by making the gold stock equal to a large-enough number of dollars. Thus the critical factor producing a depression following the end of inflation is overcome.

It cannot be stressed too strongly here how vital is the 100-percent-reserve-coin element if gold is to be used in this way. If the attempt were made to go to gold without this element, that is, with the government continuing to hold the gold and the people using paper, the effect of a sharply higher price of gold would merely be more inflation, and an actual increase in the velocity of circulation of money. For then, people would experience merely an increase in the quantity of paper dollars, which could be endlessly repeated. On the 100-percent-reserve gold-coin system, however, what people are holding is not dollars but physical gold. The velocity of money is then determined by the fact that the pieces of money are gold. The pieces of gold are held tightly and the number of dollars the pieces are called is then unable to affect the rate at which the money is spent.

Thus, one major aspect of the depression problem could be solved—the contraction in spending that results when inflation is stopped.

What about the other aspect—the excessive debt burden? The transition to a 100-percent-reserve gold-coin system would be able to solve that, too. If there were no other way to solve it, gold could simply be priced high enough to give people an actual sudden increase in their revenues and incomes calculated in dollars. In such circumstances, the transition to the system would be accompanied by the equivalent of a last burst of inflation. Thus, for example, if the problem of an excessive debt burden exists in the face of the initial \$6,000 billion-plus GDP, the price of gold could be set at the point where the 780 million ounce gold GDP represents a \$7,000 billion

or \$8,000 billion GDP or however high a dollar-GDP might be necessary.

Solving the problem of “an excessive debt burden” by means of inflation in any form is a reprehensible practice. Its only justification is the necessity of avoiding mass bankruptcies, which, given the inability of today's judicial system to keep pace even with its current case load, would probably take a decade or more to get sorted out. That would mean that in the interval the economy would be largely paralyzed, because no one would know just who owned what. This must be avoided.

The effect of distributing most of the country's gold to the banks, to place them on a 100-percent-reserve basis against their checking deposits must be explained. At present it would take about \$700 billion in gold to do this, inasmuch as that is the amount of outstanding checking deposits. The transfer of this much gold to the banking system would represent an increase in its assets of approximately \$640 billion, since its present standard-money reserves are little more than \$60 billion. The addition of this much gold to the balance sheets of the banks, as reserves against their demand deposits, would permit them to take whatever writeoffs may be necessary on their existing loans and investments as the result of actual or likely delinquencies or failures on the part of their borrowers. To the extent that a substantial increase in the assets of the banking system remained, an equivalent portion of its holdings of government securities could be canceled.

Some further major positive effects of the transition to a 100-percent-reserve system would be that both the Federal Reserve System and the Federal Deposit Insurance Corporation could be abolished. They would both be rendered unnecessary and have no further function.¹²⁴

When one allows for the fact that there is privately owned gold in the United States, and that considerably more would have come in from abroad prior to having reached the point of establishing a 100 percent reserve (provided, of course, the necessary economic freedom had been established), it turns out that a conversion price in the neighborhood of \$4,000 per ounce rather than \$8,000 per ounce would probably be sufficient to maintain the preexisting level of spending in terms of dollars, even with a velocity of circulation of only 3.¹²⁵ I arrive at this figure on the basis of the highly conservative assumption of a world monetary gold stock of 2 billion ounces and the further assumption that the American economy represents about one-fourth of the world's economy. As a result, I use a figure of 500 million ounces as the estimate of our potential total gold money supply. Assuming a gold velocity of 3, our gold GDP would thus be 1.5 billion ounces rather than 780 million ounces. Given today's fiat-money GDP of \$6,000 billion-plus,

gold would have to be priced at around \$4,000 per ounce to make it possible for the 1.5 billion-ounce gold GDP to represent an unchanged dollar GDP and thus avoid a contraction in dollar revenues and incomes. Next year, of course, when the quantity of fiat money and the GDP expressed in fiat money are higher, the appropriate gold conversion price would be higher.

As before, the principle is that to avoid a contraction of spending in terms of dollars, the conversion price of gold must be set in such a way that the prospective gold-ounce GDP of the country is made at least equal to the country's GDP in dollars at the time the transition is to be made.¹²⁶

Unilateral movement toward the remonetization of gold by the United States might at some point attract a disproportionate share of the world's gold stock. Also, a considerable burden could exist in producing the exports needed to import additional gold. Although this latter problem would be minimized through larger imports of gold while it is still relatively cheap (including imports in exchange for the sale of the kinds of government assets described earlier), a further problem could remain. Namely, the problem of the American economy becoming adjusted to the use of a disproportionate amount of the world's gold, which was then followed by other countries going over to gold. At that time, the United States might begin experiencing substantial gold outflows—in effect suffering a kind of deflation in gold.

This leads to the conclusion that it would be desirable if the conditions for the remonetization of gold could be established internationally, with the simultaneous cooperation of as many of the world's economically important countries as possible.

However, even if the United States alone moved toward the remonetization of gold, and did import a disproportionate share of the world's gold supply, the loss to American citizens as individuals would be substantially less than under the fiat-money system. Under the fiat-money system, every year the great majority of individual citizens in effect import fiat money in exchange for goods or services. For the great majority of citizens finish the year with a larger holding of fiat money than they began it, and have had to trade away goods and services to do so. This is the withdrawal-of-wealth effect I described earlier.¹²⁷ It is the necessary outcome of increases in the quantity of money, which always end up in the cash holdings of the citizens. But unlike gold, whose supply increases only modestly from year to year, with fiat money there is no end to the process short of the destruction of the fiat money in a currency collapse.¹²⁸

If American citizens imported excess gold, not only would there be a complete end to that process, but they

could probably count on later exporting the gold at a higher value, when foreign countries finally did come to move toward the remonetization of gold. Thus, their loss on this account would not be permanent. In fact, if they used most of any excess gold coming in merely to build up their gold holdings, and did not gear their normal financial activities to its presence, they would substantially benefit in the long run by their country being the first to move toward the remonetization of gold. This is because they would acquire gold at a relatively low value, when only they wanted it for more extensive monetary use, and then give it back to the rest of the world at a higher value, when everyone else also wanted it for such a purpose. And, not having geared their financial operations to its presence, they would not suffer substantial deflationary effects by virtue of its outflow.

The 100-Percent-Reserve Gold Standard, Liquidity, and the Dismantling of the Welfare State

The above proposal for the establishment of a full 100-percent-reserve gold standard in place of the present, fiat-money system has major implications for the dismantling of the welfare state—beyond the fact that it would compel the government to operate with a balanced budget. The fact that it would establish great financial liquidity, that is, large holdings of gold money relative to spending, and, of course, at the same time, reduce the burden of debt to manageable proportions, means that it would be possible radically to reduce the size of the government's budget, and the scope of government activity, without fear of causing a depression and mass unemployment.

Under present monetary conditions, if government spending were substantially reduced, the effect would be a major problem of readjustment and would probably entail a depression. This is because under present monetary conditions, the debt structure stands like a house of cards and the least failure of demand anywhere in the economic system is capable of producing a wave of bankruptcies and bank failures. But it would certainly not be true if the economic system possessed the high degree of liquidity that a 100-percent-reserve gold standard could give it.

If firms possessed both substantially larger cash reserves and smaller debts relative to their revenues and incomes, they would be able to ride out the kind of temporary, localized failures of demand that would accompany slashing the government's budget. They would be in a position of financial strength comparable to what existed in 1946.

It has been forgotten, but between 1945 and 1946—a period of just one year—federal government spending in the United States was reduced by more than 50 percent

(from \$93 billion to \$46 billion) and more than *ten million government employees—most of the army and navy—were dismissed!* This was the conversion from the war economy to a peacetime economy.

At the time, many people feared that the result would be mass unemployment and a resumption of the depression. The actual effect was not unemployment, but a rapid and radical change in the type of employment. The millions of former soldiers and sailors and war workers quickly changed jobs and began producing goods and services of value to the lives and well-being of individuals. The net effect was simply an enormous rise in the standard of living.

All this was possible because the tremendous financial strength of the economy—indicated by a velocity of circulation of money of less than 2 in 1946—guaranteed that as government spending fell, private spending would increase correspondingly. For there was simply no need to build up liquidity any higher than it already was.

Transition to a 100-percent-reserve gold standard could achieve comparable financial strength today. On the basis of it, the American economic system could experience a far more dramatic improvement than it did in 1946. Then, improvement came because the United States was able to disband an American army that had fought on foreign soil in the defense of the United States. Today improvement would come from the disbanding of a virtual enemy army that operates on American soil against the American people—namely, the massive government bureaucracy that redistributes and consumes the American people's wealth while doing its utmost to stop them from producing it. Disband this enemy army, and the output of goods and services in the United States will skyrocket.

Thus, the 100-percent-reserve gold-coin standard is a critical element in the economic reconstruction of the United States. It could stop inflation without depression and set the stage for the rapid and radical reduction of government activity.

Notes

1. For a typical instance of the treatment of inflation as caused either by "demand pull" or by "cost push" and the consignment of increases in the quantity of money to the demand-pull category, see Paul Samuelson and William Nordhaus, *Economics*, 13th ed. (New York: McGraw Hill Book Company, 1989), pp. 324–326.

2. See above, pp. 503–505 and 519–526.

3. See above, Figure 17–1, on p. 811.

4. The reader should note the parallelism here to my earlier refutation of the fallacy that falling prices caused by increased production constitute deflation. There, I showed that falling prices caused by increased production in the face of a fixed aggregate demand for goods do not reduce the ability of debtors to repay their debts because as the result of the same phenomenon that reduces prices—namely, the increase in supply—they have an inversely proportionate larger quantity of goods to sell at the lower prices. Thus it is no more difficult for them than it was before to earn any given sum of money with which to repay their debts. See above, p. 574. And, of course, to the extent falling prices increase real disposable income, the difficulty of repaying debt is actually reduced.

5. To some extent, creditors too might suffer a loss in the money value of their assets—namely, in cases in which value of the property destroyed exceeded the value of the owners' equity. But on the whole the loss of the stockholder/debtors would be far greater.

6. See above, pp. 578–579.

7. This average unit cost, and the value of the capital as well, reflects the payment of wages no less than the purchase prices of capital goods.

8. The fact that reductions in supply would tend to be associated with a lower economic degree of capitalism and a lower degree of capital intensiveness means that if the process of capital decumulation and decline in production began subsequent to the date of the balance sheet of Figure 19–2, the total monetary

value of the assets of the average business firm would be less in Figure 19–3 than in Figure 19–2. They would not be less only if the balance sheet of Figure 19–2 represented merely a point in an already established condition of capital decumulation and falling production, or if the capital decumulation and falling production were entirely the result of a fall in the productivity of capital goods rather than of a fall in the economic degree of capitalism and degree of capital intensiveness. 9. In Figure 19–1, the rate of profit and interest rise from 11.11 percent in *Year 1* (i.e., $^{200}/_{1,800}$) to 17.6 percent in *Year 3* and thereafter (i.e., $^{300}/_{1,700}$).

10. The very question of a transitional rise in the rate of profit relative to the rate of interest would not even come up insofar as capital decumulation and the fall in production were the result of a fall in the productivity of capital goods rather than in productive expenditure and the relative demand for capital goods.

11. This discussion closely parallels, *mutatis mutandis*, the discussion above, on pp. 817–818, concerning why no element of deflation is present in the fall in the rate of profit that results from a fall in the rate of net consumption and accompanies the early stages of the fall in prices that is caused by capital accumulation and economic progress. Also, in parallel with other discussion in the same place, it should be realized that any conceivable gain of business debtors at the expense of creditors resulting from a rise in the rate of profit would still not be the result of rising prices. If it could exist at all, it would be the result exclusively of the rise in the rate of net consumption and rate of profit, and would be capable of existing even if somehow there were no fall in production and supply and no rise in prices.

12. For a refutation of the fallacy that falling prices caused by increased production constitute deflation, see above, pp. 573–580.

13. Indeed, as I will show, in order for inflation or deflation to exist, it is not necessary that changes in the price level actually

exist at the moment. Changes in the price level are merely a symptom of inflation or deflation, not the phenomenon itself. The phenomenon itself can exist prior to and even in the absence of its symptoms, just as an illness can exist prior to and in the absence of its symptoms. On this subject, see below, pp. 921–922.

14. See above, the reference to Samuelson and Nordhaus for a typical textbook presentation of the demand-pull/cost-push doctrine.

15. See above, pp. 200–201.

16. See above, *ibid.*

17. On these points, see above, pp. 591–592.

18. See above, pp. 179–180.

19. See above, p. 229.

20. See below, pp. 931–933.

21. See above, pp. 899–901.

22. See above, pp. 518–519.

23. See above, Table 12–1, on p. 523.

24. See above, pp. 505–506.

25. On this subject, see above, pp. 829–831, and below, pp. 925–928.

26. See above, Table 12–1, on p. 523.

27. Rothbard originally used a similar definition. Cf. Murray N. Rothbard, *Man, Economy, and State*, 2 vols. (New York: D. Van Nostrand Company, 1962), 2:851. In his later, popular writings, however, he has come to use inflation as a synonym for rising prices.

28. On these points, see above, pp. 895–897.

29. Cf. Ludwig von Mises, *Human Action*, 3d ed. rev. (Chicago: Henry Regnery Co., 1966), p. 424. See also, *idem*, “Inflation and Price Control” in *idem*, *Planning For Freedom*, 4th ed. enl. (South Holland, Ill.: Libertarian Press, 1980), pp. 78–80. These pages also contain a valuable discussion of the semantic difficulties created by the definition of inflation as rising prices.

30. Cf. Ludwig von Mises “Planning for Freedom” in *idem*, *Planning For Freedom*, pp. 13–14.

31. See above, pp. 888–889. See also below, 940–941, which demonstrate an additional major deflationary consequence of government budget deficits.

32. At the same time, of course, because increases in the supply of gold are a by-product of increases in productive ability in general, the effect of any impairment of productive ability is a tendency toward a lesser rate of increase in the world’s overall supply of gold.

33. Just as deficits can exist without inflation, so inflation can exist without deficits. Inflation can exist even in the face of current government budget *surpluses*. It exists so long as the quantity of money is being increased at a rate more rapid than the increase in the supply of precious metals. If, while the government operates with a current budget surplus, the central bank or the private banking system buys up already outstanding government securities or acquires any other assets by means of such newly created money, there is inflation. Inflation existed under just such circumstances in the United States in the 1920s.

34. The threat of an absolute loss of gold reserves was diminished by virtue of the existence of National Bank notes and Federal Reserve notes, which served virtually to eliminate gold coin as a normal part of people’s cash holdings and thus the role of gold coin in day-to-day financial transactions. (See above,

pp. 508–509.) To the extent that gold coin is used as currency, any creation of additional paper or checkbook money is automatically followed by redemptions of paper for gold, as people seek more gold coin to keep pace with larger holdings of money overall—much as they seek more bills of the various denominations when the supply of money increases. The elimination of gold coin as a significant component of the day-to-day money supply, served to limit the loss of gold reserves to the portion flowing abroad, until such time as the citizens might become alarmed about the situation.

35. See above, p. 510.

36. See the preceding note and above, p. 509.

37. See above, pp. 504–505.

38. See below, pp. 931–933. In addition, it should be realized that as far as government debt is held by the Federal Reserve System, the payment of interest by the Treasury is largely in name only, since much of the interest is turned back to the Treasury. What this refers to is the fact that when the Treasury pays interest on debt held by the Federal Reserve System, that interest is revenue to the Federal Reserve System on which, after deducting its expenses, the Federal Reserve System earns a profit. A major portion of this profit is then turned over by the Federal Reserve System to the Treasury, just as any other government enterprise must turn over most of its profits, if any. (The Federal Reserve System is in the highly unusual position for a government enterprise of having profits because its leading product—paper money—has virtually no cost of production.) Thus, in essence, what occurs is that one department of the government—the Treasury—pays interest to another department of the government—the Federal Reserve System—on loans granted out of newly created money, and then receives much of that interest back.

39. It should not be forgotten, of course, that the economy-wide average rate of profit and interest is high precisely because of the continued existence of substantial deficits, which have the effect of raising the rate of net consumption. On this point, see above, pp. 829–830.

40. Not surprisingly, under any of the proposals for a constitutionally balanced budget, the provisions could be evaded fairly easily.

41. A loss would be self-defeating because it would reduce the government’s ability to spend, while what the government wants is to increase its ability to spend.

42. See above, pp. 888.

43. See below, pp. 930–941.

44. For a critique of this fallacy, see above, pp. 573–580.

45. See above, pp. 876–878 and 887–888.

46. See above, pp. 890–891, 591–592, and 594.

47. See above, pp. 513–516 and 519–526. See also above, pp. 916–917, where the fact that inflation causes wage rates and prices to outrun the increase in aggregate demand is explained.

64. On these points, cf. von Mises, *Human Action*, pp. 549–550.

65. See below, pp. 935–936, for a demonstration of the fact that the loss of the lender is actually substantially greater than the gain of the borrower in cases of this kind.

66. See above, pp. 520–521.

67. Cf. *Human Action*, pp. 550–566.

68. See above, pp. 622–636.

69. See above, p. 929. See also above, p. 555.

70. Cf. *Human Action*, pp. 548–550, 556.

71. See above, pp. 744–750, on the nature of this relationship.

72. On these points, see above, pp. 618–642.

73. See above, pp. 632–634.

74. See above, pp. 683–685 and 694–696

75. These cash reserves, of course, do not leave the economic system but return to business firms. On average, a business firm ends up with the same cash it had before, but it does so in an environment in which the volume of its financial transactions is greater. Thus, its cash reserves fall relative to the volume of its financial transactions.

76. Concerning all four of the mechanisms by which a more rapidly growing quantity of money reduces the demand for money for holding and thus raises the velocity of circulation of money, see above, pp. 519–522.

77. See above, pp. 513–514.

78. As a general principle, the deflationary effect of the inflation of paper money hinges on the gold value of the paper falling in greater proportion than the increase in the supply of paper money and thus the increase in the volume of spending that takes place in terms of paper money. This outcome is virtually certain inasmuch as the market takes into account in the present all of the prospective future decline in the value of paper money expected to result from inflation in the future.

79. Cf. *Human Action*, pp. 797–798.

80. See above, pp. 591–592.

81. See above, p. 591.

82. This does not mean that I advocate simply that the government abandon its policy of inflation in the context of our present monetary system. Such a step, taken by itself, would result in a catastrophic deflation and depression, probably worse than that of 1929. A disaster of this magnitude must certainly be avoided. It can be avoided if the abandonment of inflation is coupled with a transition to a 100-percent-reserve gold stan-

dard. On this subject see below, pp. 959–962.

83. See above, pp. 937–938.

84. Cf. Henry Hazlitt, *Man vs. The Welfare State* (New Rochelle, N. Y.: Arlington House, 1970), pp. 147, 148.

85. Cf. *Human Action*, pp. 426–428. See also Ludwig von Mises, *Stabilization of the Monetary Unit—From the Viewpoint of Theory*, chap. 1, in Ludwig von Mises, *On the Manipulation of Money and Credit*, trans. Bettina Bien Greaves, ed. Percy L. Greaves, Jr. (Dobbs Ferry, N. Y.: Free Market Books, 1978), pp. 3–16.

86. See above, pp. 520–521. See also above, p. 906.

87. Calculations based on data appearing in *Federal Reserve Bulletin*, October 1986, p. A13, and March 1989, p. A13.

88. See above, p. 924.

89. On the subject of credit crunches, see above, pp. 939–940. Concerning profit squeezes, see above, p. 943.

90. For the explanation of why not, see above, pp. 931–933.

91. See above, *ibid.*

92. In the discussion that follows, I frequently refer to the U. S. government rather than to the Federal Reserve System, which is merely the specific government agency charged with the formulation and execution of the government's monetary policy. I attach no great significance to the Federal Reserve's alleged independence from the government. It is, as I say, a government agency. The members of its board of governors are all nominated by the president and confirmed by the Senate. All must stand for periodic reappointment. All are subject to various political pressures. For example, many, if not all, can be assumed to have joined in various political alliances and incurred various political debts in the course of their careers prior to their appointment, debts which they can be called upon to repay during their tenure in office. In addition, of course, Congress can at any time change the law under which the Federal Reserve operates, something to which the Federal Reserve Board is very sensitive.

93. For the most part, it doesn't even actually have to create very many of those billions—its demonstrated willingness to create them is sufficient. For example, the government could create all the billions of paper currency necessary to redeem all the bank deposits in the United States. But it will never actually have to redeem any very major portion of those deposits so long as it demonstrates its willingness to do so whenever put to the test.

94. See above, this page, n. 87.

95. Calculation based on data appearing in *Federal Reserve Bulletin*, March 1989, p. A13.

96. Calculations based on data appearing in *Federal Reserve Bulletin*, March 1989, p. A13; *ibid.*, April 1993, p. A14.

97. Calculations based on data appearing in *Federal Reserve Bulletin*, April 1993, p. A14, and July 1994, p. A14.

98. As previously noted in Chapter 12, n. 34, this calculation is based on year-end data appearing in *Federal Reserve Bulletin*, July 1994, p. A14, and weekly money supply figures as reported in *New York Times*, October 17, 1994.

99. See above, pp. 520–521, for the explanation of why increases in the quantity of money raise the rate of interest rather than reduce it.

100. By way of a postscript to the discussion in the text, I must observe that as of the early spring of 1995, the international currency markets are confirming this view. The precipitating

cause seems to be the failure of the new, Republican-controlled Congress to enact a balanced-budget amendment to the Constitution, and the interpretation of this fact as signifying continued rapid growth in the U.S. national debt and a corresponding long-term need to inflate in order to service the debt. In response to such anticipations, there is a tendency in the world market to liquidate assets denominated in dollars, and use the proceeds to purchase assets denominated in other currencies, which, for the time being, are believed to have less inflationary prospects.

As a further postscript, as this book goes to the printer in the spring of 1996, it has become clear that since the end of 1993, an important development has occurred with respect to what should be counted in the M_1 money supply. Over this time, general-purpose and broker-dealer money-market-mutual-fund accounts have rapidly become indistinguishable from ordinary checking accounts, in that requirements limiting the frequency with which checks may be written on these accounts, as well as requirements limiting the minimum-sized check that may be drawn on them, have both been rapidly disappearing. In the absence of further research, it is not possible to determine the precise amount of growth in the money supply for which this development has been responsible in the last two years. But taking it as equal merely to the increase in these accounts over this time, the effect on the rate of increase in the money supply has been substantial, even if one includes in the money supply at the end of 1993, the totality of such accounts rather than merely the fraction of them that was already the equivalent of checking accounts at that time.

Based on the data in the *Federal Reserve Bulletin* of March 1996, p. A14, the effect of recalculating the growth in the reported M_1 money supply in this way is that the percentage change between December 1993 and December 1994 becomes 3.2 percent instead of 1.7 percent, and the percentage change for 1995 becomes +4.1 percent instead of -2.2 percent. The significance of such recalculation is that it makes intelligible what would otherwise be an extremely puzzling phenomenon indeed. Namely, how the economic system could be displaying signs of inflation in the midst of fairly sustained outright deflation.

101. See above, pp. 141–144.

102. Concerning the origin of money, see above, pp. 506–508.

103. *Roman Civilization Sourcebook II: The Empire* (New York: Harper & Row, 1966), p. 440.

104. *Ibid.*, pp. 441–442. This was like insisting today that a \$20 gold coin be used as the equivalent of only \$20 of paper money.

105. See James Breasted, *Ancient Times*, 2d ed. (Ginn and Company, 1967), p. 747.

106. On this point, see above, pp. 510–511. See also below, pp. 951–954.

107. This, of course, is the process of good money driving out bad money. For reconciliation of this fact with Gresham's Law, according to which bad money drives out good money, see above, pp. 510–511.

108. Henceforth, for the sake of brevity, I generally refer to gold alone. But the same points apply to silver as well.

109. One method of estimating the proper conversion price is simply to divide the government's existing gold stock into the money supply. Currently, this means dividing approximately 260 million ounces of gold into \$1,128 billion of money. The

resulting conversion price is thus \$4,340 per ounce. When the monetary role of silver is allowed for, however, a figure of closer to \$3,000 results. Concerning this last, see below, pp. 958–959.

110. On the subject of the monetary unit as a unit of weight of precious metal, see Murray Rothbard, *What Has Government Done to Our Money?* (Novato, Calif.: Libertarian Publishers), 1974, pp. 5–7.

111. See above, pp. 573–580 and 817–818.

112. See above, pp. 762–767, 774–775, 807–818, and 825–826.

113. See above, p. 574 and pp. 744–750, 762–771, and 882–883.

114. See above, pp. 519–526 and 938–940.

115. Recognition of the fact that a greater demand for money for holding increases the real stock of money and, indeed, is the only thing that can do so, can be found in Rothbard, *What Has Government Done to Our Money?*, pp. 15–16. See also above, pp. 693–694.

116. This figure follows from the fact that total checking deposits were approximately \$799 billion, while bank reserves of standard money were approximately \$61 billion. See *Federal Reserve Bulletin*, July 1994, pp. A13, and A14.

117. *Ibid.*, p. A29.

118. On the subject of parallel standards, see Rothbard, *What Has Government Done to Our Money?*, pp. 17–19.

119. This section is largely a revised version of my article "Gold: The Solution to Our Monetary Dilemma," which appeared in the *Bulletin of the US Paper Exchange*, June 1980, and was subsequently reprinted in *The Intellectual Activist*, October 1 and November 1, 1980.

120. See *Federal Reserve Bulletin*, July 1994, pp. A14, A51.

121. See above, pp. 263–278, for explanation of the ways that price controls and socialism destroy material civilization.

122. For the sake of simplicity, we ignore the role of silver.

123. I am indebted to Murray Rothbard for this pattern of achieving a 100-percent-reserve gold standard, which he first presented in an unpublished monograph in the mid-1950s.

124. *Ibid.*

125. When the monetary role of silver is allowed for, the conversion price works out to closer to \$3,000 per ounce.

126. In certain circumstances, compliance with this principle might require that the government use less than its full gold stock to redeem the supply of paper currency and fiduciary media. For example, if the U.S. government today possessed 500 million ounces of gold by itself, the conversion price implied by devoting all of it to the redemption of the money supply would be only \$1,500 per ounce. This would make the gold-ounce GDP, and the volume of spending it implies, the equivalent of too few dollars to comply with the principle. In such circumstances, the government could devote less than its full gold stock to the redemption of the outstanding money supply, and use the remainder in redeeming a portion of the national debt. In other circumstances, of course, the government's gold stock might be so limited that it would be necessary to increase it before making the conversion.

127. See above, pp. 936–937.

128. The additional holdings of gold on the part of the citizens have the further distinction at least of representing an additional supply of a physical commodity, which is capable of making some actual contribution to human well-being.

EPILOGUE

CHAPTER 20

TOWARD THE ESTABLISHMENT OF LAISSEZ-FAIRE CAPITALISM

1. Introduction

The principles and theories presented in this book call for a society of laissez-faire capitalism. (For the sake of brevity, I often refer simply to a capitalist society. In such cases, it should be understood that laissez-faire capitalism is the only logically consistent form of a capitalist society.) If such a society is to be achieved, a political movement pursuing a long-range program will be necessary. My purpose in this concluding, epilogue chapter is to describe the nature of such a movement and to offer a basic outline of the long-range political program it would have to follow, including a description of how the most difficult steps in the program might actually be accomplished. As far as I know, my effort here is the first of its kind; as such, it will undoubtedly benefit greatly from the numerous additions and refinements that I hope others will be led to make.

The Importance of Capitalism as a Conscious Goal

The first thing that those in favor of capitalism must do is to make the conscious, explicit decision that they seriously want to achieve a fully capitalist society and are prepared to work for its achievement. We need to view ourselves as active agents of change, working toward a definite goal: laissez-faire capitalism.

The advocacy of laissez-faire capitalism, indeed, of capitalism in any explicit form, has not been present in the political spectrum. In the United States, the political controversies of the last several generations have been

carried on between the “liberals,” who stand for socialism, and the “conservatives,” who stand for nothing except what other groups, including the liberals, have managed to establish as the country’s tradition.

The success of the liberals/socialists in enacting their program shows that what we need is a group of educated and articulate individuals who adopt the achievement of *capitalism* as their goal. Such individuals, dedicated to maintaining constant progress toward capitalism, would constitute a de facto capitalist political party, even if the name of such a party never appeared on a ballot. By virtue of constantly offering their own definite program for political change, they would seize the political initiative. Instead of merely attacking the socialistic proposals of the “liberals” and then yielding to them and abandoning the fight once the proposals happened to be enacted, as is the almost invariable practice of the conservatives, they would always strive to move in the direction of capitalism. As an essential part of the process of doing so, they would never tire of assaulting intellectual targets as far behind enemy lines as possible—such as social security, antitrust legislation, and public education. Never would they accept the existing state of society as immutably given and deserving of preservation merely because it exists. Always they would seek to change the existing state of society until it represented laissez-faire capitalism.

Laissez-faire capitalism would represent their fixed star so to speak. To the extent that present conditions departed from it, they would be radical in seeking to

change present conditions. To the extent that conditions in the past had approximated laissez-faire capitalism, they would be reactionary in seeking to reestablish such conditions. To the extent that present conditions were consistent with laissez-faire capitalism, they would be conservative in seeking to preserve those conditions.

The program such a party would have to follow is both political and educational in nature. It is political in that it centers on the offering of specific political proposals, which, if adopted, would move the country toward capitalism. It is educational in that it views the basic problem that we face as one of explaining to the people of the United States and other countries the value of a capitalist society and the value of the specific steps required to achieve it. What people do is determined by what they think. If we want to change the political practice, there is no other way but to change people's political philosophy and economic theories. Accordingly, every political proposal that I suggest is itself intended to serve as a vehicle for educating the public and for attracting talented individuals to our cause who in turn will become capable of educating still others to the value of our program.

Needless to say, the substance of such education is the spread of the ideas of Ludwig von Mises and Ayn Rand, reinforced by the ideas of other procapitalist economists and philosophers whom I mentioned in the Introduction and elsewhere in this book. It is principally owing to the great popular success of the writings of Ayn Rand and the growing influence of the works of Ludwig von Mises that there already exists a significant and growing number of potential recruits for the procapitalist political movement that I envision. The further spread of the ideas of these two historic figures is the only possible basis for the further growth and ultimate success of the procapitalist cause.

Along these lines, I wish to acknowledge once more how important are all philosophic ideas that determine people's conception of the position of the human individual in relation to the world in which he lives. For example, so long as man is viewed as fundamentally helpless, with his destiny controlled by forces beyond his power to change, it will be next to impossible to eliminate the welfare state. People will cling to it out of a sense of helplessness. Elimination of the welfare state and the establishment of a capitalist society presupposes a view of man as a self-responsible causal agent, capable of securing his well-being by means of intelligent action. Indeed, the entire program of reform outlined in this chapter must proceed alongside a renewal of all of the philosophical foundations of a division-of-labor, capitalist society that I described in the first chapter of this book.¹ It is this above all which makes the dissemination

of the ideas of Ayn Rand so important. As the leading advocate of reason in modern times, her writings alone hold out the possibility of the necessary fundamental philosophic changes taking place in our culture, without which efforts at the level of economic theory and political philosophy are doomed to failure.

In the pages that follow, I write of political campaigns over various issues. Please understand that I am not writing merely or even primarily of campaigns carried out in connection with elections. Rather, I am writing of campaigns carried on year in and year out, as part of a process of continuous education of the public. Each of these campaigns would necessarily have to be preceded and accompanied by the writing and dissemination of an appropriate literature, ranging from books and monographs on down to handbills—a literature dealing with the specific issues at hand, but always in relation to wider, abstract principles. Indeed, the dissemination of such literature and its articulation in speeches and debates would constitute the substance of what I call political campaigns.

Further, I think that to achieve capitalism it will ultimately be necessary for a formally organized capitalist party to come into existence, whose primary function will actually be to serve as an *educational institution*: it would have one or more book-publishing houses, theoretical journals, magazines devoted to current issues, and schools turning out intellectual leaders thoroughly versed in economic theory and political philosophy. All of these vehicles would be devoted at least as much to questions of political philosophy and economic theory as to political activity.

The political proposals I make are short- and intermediate-range, as well as long-range in nature. I believe that it will take several generations to achieve a fully capitalist society, mainly because of the time required for the educational process. It will not be enough just to present our long-range goals. It will be necessary to advocate a whole intervening series of short- and intermediate-range goals whose enactment will represent progress toward our long-range goals. The major political task in the years ahead will be continuously to formulate such short and intermediate range goals, and to keep the country moving in the direction of full capitalism by means of their successive achievement. The short- and intermediate-range goals I offer are intended to illustrate principles of strategy and tactics and thus to serve as a pattern.

In the light of the preceding, it should scarcely be necessary to say that at no time should the advocacy of sound principles be sacrificed to notions of political expediency, advanced under misguided ideas about what is "practical." The only practical course is to name and

defend true principles and then seek to win over public opinion to the support of such principles. It is never to accept the untrue principles that guide public opinion at the moment and design and advocate programs that pander to the errors of the public. Such a procedure is to abandon the fight for any fundamental or significant change—namely, a change in people’s ideas—and to reinforce the errors we want to combat.

It is definitely not impractical to explain to people that if they want to live and prosper, they must adopt capitalism. It would not be impractical to do so even if for a very long time most people simply refused to listen and went on supporting policies that are against their interests. In such a case, it would not be the advocates of capitalism who were impractical, for they would be pursuing the only course that is capable of working, namely, explaining to people what they must do if they are in fact to succeed. Rather it would be the mass of people—perhaps, indeed, the entire rest of the society—that would be impractical, pursuing as it did goals which are self-destructive and refusing to hear of constructive alternatives. If, to use an analogy from the world of engineering and business, someone knows how to build an airplane or a tractor that people could afford and greatly benefit from, but is not listened to, such a person is not at all impractical because others refuse to listen to his ideas that would greatly benefit them. Rather it is those others, whatever their number, who are impractical. In the political-economic realm, it is the current state of public opinion that is impractical: it expects that men can live in a modern economic system while destroying the foundations of that system—that, for example, they can have rising prosperity while destroying the incentives and the means of the businessmen and capitalists who are to provide the prosperity. The advocates of capitalism, who tell people that the opposite is true and that the opposite policy is necessary, are not impractical. They are eminently the advocates of practicality—of what is achievable in, and by the nature of, reality.

It is the grossest compounding of confusions to suggest that those who know truths that masses of impractical people refuse to hear, accept error as an unalterable given for the sake of which they must abandon or “bend” their knowledge of the truth. Nothing could be more impractical, elevating as it does, error above truth and making knowledge subordinate to ignorance. The essence of true political practicality consists of clearly naming and explaining the long-range political program that promotes human life and well being—i.e., capitalism—and then step by step moving toward the fullest and most consistent achievement of that goal. That the initial effect of naming the right goal and course may be to shock masses of unenlightened people and invoke their

displeasure should be welcomed. That will be the first step in awakening them from their ignorance.

It should not be surprising that those who fear the effects of the open advocacy of capitalism are themselves highly deficient in their knowledge of capitalism. They fear to evoke the displeasure of the ignorant because they do not know enough about capitalism to know what to say in the face of such displeasure. Their ignorance on this score, I believe, is the result of an unwillingness to acquire a sufficient combination of knowledge of political philosophy and economic theory, above all, of economic theory. Remnants of the mind-body dichotomy in their thinking prevent them from fully grasping the intellectual—indeed, the profoundly philosophical—value of a subject as “materialistic” as economics. To be successful, the advocates of capitalism must immerse themselves in the study of economic theory.

The Capitalist Society and a Political Program for Achieving It

The capitalist society we want to achieve is a society in which individual rights are consistently and scrupulously respected—in which, as Ayn Rand put it, the initiation of physical force is barred from human relationships. We want a society in which the role of government is limited to the protection of individual rights, and in which, therefore, the government uses force only in defense and retaliation against the initiation of force. We want a society in which property rights are recognized as among the foremost human rights—a society in which no one is made to suffer for his success by being sacrificed to the envy of others, a society in which all land, natural resources, and other means of production are privately owned. In such a society, the size of government would be less than a tenth of what it now is in terms of government spending. Most of the government as it now exists would be swept away: virtually all of the alphabet agencies and all of the cabinet departments with the exceptions of defense, state, justice, and treasury. All that would remain is a radically reduced executive branch, and legislative and judicial branches with radically reduced powers. To the law-abiding citizen of such a society, the government would appear essentially as a “night watchman,” dutifully and quietly going about its appointed rounds so that the citizenry could rest secure in the knowledge that their persons and property were free from aggression. Only in the lives of common criminals and foreign aggressor states would the presence of the government bulk large.

If these brief remarks can serve as a description of the capitalist society we want to achieve, let us now turn to a series of political proposals for its actual achievement. I group the proposals under seven headings: Privatization

of Property, Freedom of Production and Trade, Abolition of the Welfare State, Abolition of the Income and Inheritance Taxes, Establishment of Gold as Money, Pro-capitalist Foreign Policy, and Separation of State from Education, Science, and Religion. Under each of these heads, I develop specific issues and programs each of which deserves to be fought for and which, in being fought for, would serve to promote the spread of our entire political-economic philosophy.

2. Privatization of Property: Importance of Fighting on Basis of Principles

The privatization of property is the most fundamental aspect of a procapitalist political program. In addition, its discussion is well suited to illustrate strategy and tactics applicable to the pursuit of *all* aspects of a procapitalist political program.

Privatization would ultimately require the sale of all government-owned lands and natural resources (with such limited exceptions as the sites of military bases, police stations, and courthouses), which presently include the greater part of the territory of many of the Western states and almost all of the territory of Alaska. It would entail the sale of TVA and all other public-power facilities, the sale of Amtrak and Conrail, the post office, the public schools, universities, and hospitals, the national parks, and the public highway system. It would also entail the establishment of the airwaves as private property and of private property rights under the sea and in outer space.

Those of us who work to establish capitalism must always be aware that the privatization of all of these things is part of our ultimate goal and we must be sure that all new adherents we gain fully understand and support the whole program of privatization, as well as all the other essential aspects of our program. No secret must ever be made of the full, long-range program and its goal of complete laissez-faire capitalism.

In the present situation, I believe that the most important aspect of privatization to concentrate on is that of the federal government's vast landholdings, in particular where oil, coal, and timber are concerned. Closely connected with this should be the urging of the extension of private ownership to undersea mining operations. These aspects would make it possible to link the campaign for privatization with an assault on the environmental movement, which has replaced socialism as the leading threat to material civilization. Such linkage would provide the opportunity to reestablish the rightful connection between capitalism, on the one side, and science, technology, economic progress, and the supreme value of human life on earth, on the other side. This connection has been

concealed for many years because of socialism's usurpation of the mantle of progressivism. Linkage of the campaign for privatization with an assault on the environmental movement would be instrumental in reestablishing capitalism in the minds of the public as the system of progress and improvement advocated by men of reason, and the opposition to capitalism as the manifestation of ignorance, fear, and superstition.² A further major aspect of the linkage should be a continual hammering away at the appalling state of contemporary education and the ignorance of its graduates, including almost all of today's politicians, government officials, and journalists. The environmentalist and socialist opposition to capitalism should be portrayed as exactly what it is—a movement to return the world to the Dark Ages and a system of feudal privilege.³ Privatization of education, of course, should be urged as an essential aspect of the rebirth of education.

Other, narrower campaigns for privatization that might profitably be conducted early on would be ones for the privatization of the post office, the airwaves, and the New York City subway system. Postal service and cellular-telephone channels are already private to varying degrees. In these two cases, privatization would merely be a matter of carrying forward something that already exists to an important extent.

The New York City subway system would be a good candidate for an early privatization campaign, because it should be relatively easy to explain how the establishment of private ownership would create an incentive for the subway's management to want to attract customers and thus to improve the cleanliness, safety, and efficiency of the system. Such a campaign would represent our going on the offensive in the country's leading bastion of collectivism and making large numbers of collectivists aware that the comfort of their daily lives depended on the acceptance of the principle of private ownership of the means of production.

Each of these individual campaigns would, of course, have to be focused on its own particular set of concretes. But if, at the same time, they were also based on the *principle* of the economic superiority and moral rightness of private ownership, the cumulative effect would be to tend to establish that principle as correct in the public's mind. Thus, provided they were conducted in the name of our basic principles and used as the opportunity for explaining those principles, success in such lesser projects would help in someday putting us in a position in which we could accomplish the objective of privatization completely.

We should certainly not expect that we would quickly win any of the campaigns for privatization, even the least among them. On the contrary, for a very long time we

would almost certainly lose them all, over and over again. Indeed, we should expect for some time to be written off as cranks and even ridiculed for our views. Nevertheless, if we fight every concrete issue on the basis of correct abstract, general principles, our efforts will never be wasted. We will be successful even though we fail to win our particular objective of the moment. We will be successful because we will have propounded and helped to spread our principles. As a result, we will have gained new adherents, who will have been attracted to our principles. In addition, those who waged the campaign will have become more skilled in the defense of their principles. Thus, we will have gained the basis for conducting campaigns over the same issue, and over a wide variety of other issues, on a stronger foundation in the future. We will be embarked upon a policy of progress in intellectual influence analogous to the process of capital accumulation and economic progress.⁴

If we are successful in making continual progress in our intellectual influence, we cannot fail ultimately to possess major intellectual influence and therefore correspondingly major political influence. To achieve the most rapid possible success, our objective should be to accomplish in terms of intellectual influence the kind of rate of progress achieved economically by Japan and other contemporary East Asian countries that began in the most humble material conditions. If we could succeed in that, then even though we may begin today in the most humble conditions in terms of size and influence, within a matter of decades we would become a major intellectual force.

As part of the same point, I want to stress that a major feature of every political activity we engage in is that it must provide easy opportunities for any new supporters it attracts to become exposed to our entire philosophy. The individual campaigns, such as the ones I have just described, must not only be waged on the basis of the appropriate abstract principles, but they must also provide ready exposure to the main books and publications of our philosophy. This does not mean that handing out copies of *Human Action* or *Atlas Shrugged* is the first or most prominent thing we do in such a campaign, but it does mean that we are very interested in making every receptive individual we meet aware of the existence of these books and in getting him to read them and the rest of our essential literature.

3. The Freedom of Production and Trade

The establishment of the freedom of production and trade implies the abolition of all government interference with production and trade. It implies, for example, the abolition of all labor legislation, licensing laws, the an-

titrust laws, and zoning laws. It implies the abolition of virtually all of the alphabet agencies. It also implies the freedom of international trade and migration.

An important principle that I think we should adopt in fighting for the freedom of production and trade is to show how *its establishment would enable individuals to solve their own economic problems*. For example, there are few more serious economic problems than mass unemployment. As we have seen, this problem is the result of the government restricting the freedom of individuals to offer and accept the lower wage rates that would make full employment possible. The restrictions are in the form of minimum-wage laws, prounion legislation, unemployment insurance, and welfare legislation. Abolishing such legislation and establishing the freedom of production and trade should be presented as the solution to this problem—as a solution that would enable the voluntary, self-interested actions of individuals to establish the terms on which everyone seeking employment could find it.⁵

In the same vein, we must take the initiative in calling for a widening of economic freedom as the solution to the problems the United States is encountering in international trade. We must show that the inability of major American industries to compete with foreign goods is the result of government intervention, and that the remedy is not the imposition of further intervention, in the form of tariffs or quotas, but the repeal of existing intervention. For example, prounion legislation causes artificially high wage rates and holds down the productivity of labor, thereby causing an artificially high level of costs for American manufacturers. The tax system and inflation have prevented the introduction of more efficient machinery, and thus have also contributed to the artificially high costs of American manufacturers, as have numerous government regulations. Such intervention should be the target of campaigns for repeal. Obviously, this would be a fertile area for the writing of books and monographs demonstrating the general principle in terms of the specific conditions of individual industries.

Similarly, the freedom of production and trade should be presented as the means of sharply reducing the cost of housing, thus making it possible for many more people to afford decent housing. The abolition of prounion legislation, building codes, zoning laws, and government agencies that withdraw land from development (such as the California Coastal Commission) would all serve to reduce the cost of housing, as would the abolition of property taxes that support improper government activities. (As should be clear from previous discussion in Chapter 10, all of these points, of course, apply to the solution of the problem of homelessness, which is greatly exacerbated by the imposition of government require-

ments concerning minimum housing standards.⁶⁾

The freedom of production and trade should also be explained as the means of sharply reducing the cost of medical care. As explained in Chapter 10, under present conditions the government restricts the supply of doctors and the number of hospitals through licensing. Its solution for the consequent inability of many people to afford medical care is then to pour more and more public money into subsidizing their medical bills. The effect of the government's spending programs is to bid the price of medical care ever higher, progressively substituting new, ever higher income victims for previous victims just below them who are added to the subsidy rolls—and, of course, to reduce the quality of medical care for all groups. The obvious real solution is to *end government interference in medical care* and thus to make possible the largest and most rapidly improving supply of medical care that free and motivated providers can offer.⁷

In sum, our theme must be the opposite of the one people are accustomed to. Instead of it being what new programs the government must undertake to solve this or that problem, it must be what *existing* government programs and activities must be *stopped*, in order to allow individuals to be able to act in their own self-interest. Instead of the question being “What can the government do?,” we must explain what it must stop doing that it now does, and that has caused the problem complained of.

We need to show how abolition of the antitrust laws would mean more competition, greater efficiency, and lower prices; how abolition of the Environmental Protection Agency would mean more efficient production and thus a greater ability of man to improve the external material conditions of his life, i.e., his personal environment; how abolition of the Food and Drug Administration would mean the introduction of more life-saving drugs; how abolition of Medicare and Medicaid, the National Institutes of Health, and all other government interference with medicine would lower the cost and improve the quality of medical care.

While fighting against all existing violations of the freedom of production and trade, a further important principle to seek to establish is *the exemption of all new industries from violations of the freedom of production and trade*. This, in fact, was one of the principal methods by which economic freedom was established historically in England: the significance of the restrictions imposed by the medieval guilds was steadily reduced by the exemption of new industries from those restrictions.

Appropriate Compromises

It should be realized that if the immediate, total abolition of a given policy of government intervention cannot obtain sufficient support to be carried out, it is proper to

work for programs of partial liberalization as temporary compromises—provided it is done explicitly and openly, in the name of the right principles, and no secret is made of our ultimate goals, which one is always prepared to defend and whose achievement serves as the standard and purpose of any temporary compromises.

Thus, for example, while openly advocating the full freedom of the housing industry, including the ultimate abolition of all building codes, one might participate in, or even launch, a campaign for a much more limited objective. Such an objective might be that the government be required to reduce the financial impact of meeting code requirements by an average of, say, X thousand dollars per house, and that it be guided by the advice of private insurance companies, mortgage lenders, and construction contractors in deciding which code requirements to modify or abolish in order to achieve this goal. Such a step would be helpful in reducing the cost of housing. A campaign for it, properly conducted, would help to make people aware that it was government intervention that was responsible for the high cost of housing and high costs in general. If carried out under the terms mentioned, a major value even of campaigns to accomplish such limited objectives would be that government intervention, not private business, would be made the target of restriction. Government force, rather than the profit motive of business, would come to be established in the public's mind as the evil that must be controlled and progressively rolled back.

Similarly, if the immediate, full freedom of medicine cannot be achieved, then, as a temporary compromise—again, presented as such and in the name of the right principles—one might work to allow merely registered nurses and licensed pharmacists to begin practicing various aspects of medicine. Such liberalization would significantly mitigate the problem at hand and, at the same time, it would promote the essential principle that more freedom is the solution to economic problems. It would thus be an important step in the right direction.⁸

The Case for the Immediate Sweeping Abolition of All Violations of the Freedom of Production and Trade

If the public possessed the necessary philosophic and economic understanding, the ideal procedure would be the immediate and simultaneous abolition of all interferences with the freedom of production and trade. This would be both on the principle of individual rights and on the principle that pressure-group warfare is inherently self-defeating. It is self-defeating in that whatever any one pressure group gains by violations of freedom made on its behalf, is reduced by what all other pressure groups gain by violations of freedom made on their behalf, and reduced by more. For example, what the workers in the

automobile industry gain in higher wages resulting from the existence of an automobile workers' union, they lose back in higher prices that they must pay for the products not only of all the unionized industries (which by itself may be very considerable), but also for the products of all industries enjoying protective tariffs or receiving government subsidies, all of which is the result of the underlying principle of government intervention. And everyone loses by virtue of the unemployment and overall reduction in the productivity of labor that result, which simply cause less to be produced and sold in the economic system. In essence what is entailed in pressure-group warfare is mutual plunder. Under such an arrangement, not only does each victim lose an amount equal to what the predator gains, but the victims produce less, with the result that there is less to plunder. The process can be pushed to the point where virtually nothing is produced and thus very little can be plundered—much less than could be obtained by honest work in a free society. The pressure-group marauders have long since carried things to the point where the real wages of the average worker are far lower than they could be.

The simultaneous abolition of as much government interference as possible would help to diminish the losses experienced by any one such protected group when its privileges were removed, and would make possible correspondingly greater gains, both in the long run and in the short run, for everyone. Thus, for example, when the wheat farmers lost their subsidy, they would be compensated by the lower prices resulting from the abolition of others' subsidies as well, along with lower prices resulting from the abolition of protective tariffs, labor-union coercion, and minimum-wage legislation. The substantial increase in production that would result would operate further to compensate them, through a fall in prices greater than any fall in the average of incomes that might result.

The special importance of abolishing pronoun legislation at the same time as minimum-wage legislation, should be obvious. This is necessary to prevent unemployed workers from having to crowd into a comparative handful of occupations at unnecessarily low wages, by opening all occupations to the freedom of competition.⁹

It is important to understand that acceptance of the principle of laissez faire and the willingness to fight for that principle is the only safeguard of the public against the depredations of pressure groups. Each pressure group is in a position in which the comparatively small number of its members is able to have a potentially substantial gain. This gain comes at the expense of a relatively small loss on the part of each of the enormously larger number of people who constitute the rest of society. For example,

if the members of a pressure group numbering, say, one hundred thousand people are to receive a subsidy of some kind, that subsidy may provide each of the recipients with \$100,000 per year in additional income, while it costs each of the far greater number of taxpayers only a small fraction of that sum. In this case, the total cost of the subsidy is \$10 billion (i.e., \$100,000 x 100,000). If there are a hundred million taxpayers, the cost of the subsidy to the average taxpayer is just \$100 per year (i.e., \$10 billion divided by 100 million). The diffuse interest of the taxpayers in saving \$100 per year each cannot remotely compare in strength with that of the highly concentrated interest of the pressure-group members who stand to gain \$100,000 per year each. Accordingly, the pressure-group members are willing to make substantial financial contributions and to engage in intense lobbying efforts in order to get their way. Virtually no individual taxpayer, on the other hand, has a sufficient incentive to do anything to counter such assaults on the country's treasury.

The taxpayers can acquire an incentive to protect themselves only when they view the depredations of each pressure group as a matter of the violation of a supreme political principle—namely, that of laissez faire—a principle whose violation by any one pressure group opens the gates to its violation by scores of other pressure groups. Taxpayers who would view the matter in terms of principle would recognize that pressure group warfare already costs them many thousands of dollars per year each in higher taxes and higher prices, and that there is no limit to its potential cost short of total financial ruin. If they could be led to view matters in this light, I believe that they could then easily be organized to overcome the pressure groups. By taking on all the pressure groups at once, they would have not only a powerful individual financial incentive, but they would also be able to play up all the inherent conflicts among the various pressure groups themselves, and thus obtain substantial support from within the ranks of the pressure-group members, a growing number of whom are also more and more harmed, the more widespread becomes the system of pressure-group warfare.

An appropriate vehicle for the establishment of the freedom of production and trade, whether all at once or gradually, would be the establishment of one last regulatory-type agency: *the Deregulation Agency*. Its powers would supersede those of any regulatory agency, the acts of state and local legislatures, and the prior legislation of Congress. In sharpest contrast to all regulatory agencies, however, its powers would be limited to the *repeal* of existing regulations and laws, including the narrowing of their scope in conditions in which considerations of

political expediency prevented their total repeal. It would have no power to enact any new or additional regulation.

The mandate of this agency would be to ferret out all regulations of any federal, state, or local government department or agency, and all federal, state, and local laws, that violated the freedom of production and trade. Ideally, the agency would possess the power to render any or all of them null and void. As a minimum, the enabling legislation for the agency should require it, within a fairly short period of time, such as three years, to reduce the cost of government interference in the economic system as a whole by a minimum of 50 percent. (This figure would not apply to spending for social security, welfare, and public education, which would follow the less-radical reduction schedules explained below.) Further reductions of at least 2 percent per year would be achieved thereafter, until the full freedom of production and trade was established. If, for Constitutional reasons, the agency could not be given the power to supersede federal legislation, its tasks would include the annual submission to Congress of the necessary legislative proposals for the repeal of existing federal laws.

4. Abolition of the Welfare State

Let me now present a program for accomplishing what many people believe to be simply impossible politically, namely, the abolition of the welfare state.

Elimination of Social Security/Medicare

The social security system, together with Medicare, could be eliminated by means of the following steps. First, following a grace period of perhaps two or three years, to provide sufficient warning and time to adjust, there should be an immediate rise in the age at which individuals are eligible to receive social security and Medicare benefits, from 65 to 70.¹⁰

As compensation for the loss of these benefits, individuals in the age bracket 65 to 70 should be made exempt from the federal income tax on whatever earnings they derive from employment. The result would not only be an enormous reduction in government expenditures, but a substantial rise in government tax revenues as well. The rise in tax revenues would come about because the people in the 65–70 age bracket would now pay more in the form of sales, excise, and property taxes, as the result of their having and spending higher incomes. And they would pay more in the form of state and local income taxes as well.

If enacted today, this part of the proposal for abolishing social security and Medicare would cut the costs of these programs on the order of a third.¹¹

But there is more. As part of the same legislation that quickly raises the social security retirement age to 70, the age at which people are eligible to receive social security and Medicare benefits should be *further increased*, say, by an additional calendar quarter with the passage of each subsequent year. Under this arrangement, individuals who wished to retire at age 70, despite the progressive rise in the social security retirement age beyond 70, would have an additional year of notice in which they would have the opportunity to accumulate additional savings to take the place of the loss of each successive three months' social security/Medicare benefits.

For example, those age 64 at the time the social security/Medicare phase-out began, would have an additional year in which to compensate for the rise in their prospective social security retirement age to 70 $\frac{1}{4}$. Those age 63 at the time, would have two additional years in which to compensate for the prospective rise in their particular social security retirement age to 70 $\frac{1}{2}$, and so on. Possibly, the additional savings such individuals would need to make could be made tax-exempt, under an IRA-type arrangement. (Savings in the government's budget achieved by the initial rise in the retirement age to 70 would help to offset the revenue loss of making these savings tax exempt.)

All by itself, the progressive rise in the social security retirement age in this way would slowly operate to abolish the system. However, I do not believe the system's demise should be allowed to drag on indefinitely. I think that no later than twenty-five years after the initial rise in the social security retirement age to 70, the system should accept its last new beneficiaries, who would then be 76 $\frac{1}{4}$. By that time, everyone would have had in excess of 25 years to make provision for his own retirement at age 76 $\frac{1}{4}$.

It should be realized that the progressive elimination of the social security/Medicare system would operate to promote savings and capital accumulation. The savings of individuals would steadily replace taxes as the source of provision for old age. The increased capital accumulation that this made possible would, of course, increase the demand for labor and the productivity of labor, which means that it would increase wage rates and the supply of goods, which latter would operate to reduce prices. Thus, real wages and the general standard of living would rise. The rise would be progressive insofar as the rate of capital accumulation was increased.

While the total abolition of social security and Medicare must always be one of our long-run goals, an immediate way to begin reducing the cost of these programs would be for the government simply to make the kind of tax-exemption offer I described above, to everyone eli-

gible to receive these programs' benefits. Namely, so long as anyone eligible to receive such benefits abstains from doing so and continues to work instead, his earnings from employment will be exempt from the federal income tax. Being enabled to keep almost all of one's earnings might make it worthwhile for many people to keep on working some years longer, rather than accept social security and Medicare. Not only would the government's outlays be reduced as the result of this measure, but, as I noted before, its revenues would almost certainly increase. If enacted, this proposal would achieve some significant immediate good, and, in addition, help to prepare the ground for further reductions in the cost of social security and Medicare.

It should also be noted here that the phaseout of the social security and Medicare programs, or the undertaking of any other measure that would be accompanied by an increase in the number of people seeking employment, calls for an intensification of efforts to abolish or restrict as far as possible prounion and minimum-wage legislation. This is necessary in order to make it possible for the larger number of job seekers to find employment.

Elimination of Public Welfare

The public-welfare system, including food stamps and rent subsidies, could be substantially eliminated within a few years. What would need to be done is to begin reducing welfare payments for able-bodied adults and for minors above the age of fourteen by, say, 10 percent per year across the board, until those payments fell substantially below the wages of the lowest-paid workers. Aid to dependent children below the age of fourteen could be gradually abolished by a law declaring children born more than one year after its enactment to be ineligible for receipt of such aid. Henceforth, dependent children of welfare recipients would have to be supported out of the welfare payments of their parents, which would be steadily reduced. Thus within a few years, welfare for able-bodied adults would cease to be economically significant, because all such adults would be confronted with a situation in which they would be substantially better off taking even the lowest-paid jobs. Within fifteen years, aid to dependent children would cease entirely, whereupon the whole welfare program would be without economic significance.¹²

As previously noted, at the same time that welfare benefits were being reduced, legislation limiting employment opportunities would also have to be abolished or at least progressively restricted, such as the minimum-wage laws and prounion legislation.¹³ In addition, restrictions on the employment of teenage juveniles would have to be eliminated in conformity with the immediate reductions in welfare allowances to teenage children. The abolition of

these restrictions on employment opportunities are necessary to provide people presently receiving welfare benefits with a realistic alternative of living by working. Finally, the reduction in government expenditures for welfare could be earmarked for increasing the personal exemption from the income tax of people who are gainfully employed. This would further increase the economic advantages of working over being on welfare.

My reason for suggesting the gradual reduction in welfare benefits rather than their immediate or very rapid total elimination, is to allow time for large concentrations of people on welfare, such as in Harlem in New York City, to move to areas that offer better prospects for employment; and, at the same time, for new industry to move into areas such as Harlem, in response to the existence of large numbers of people willing to work for low wages. The gradual reduction in welfare benefits would also allow time for private charitable efforts to develop to deal with the cases of individual suffering not caused by the fault of the individuals themselves.

Once public welfare benefits were reduced to a level substantially below the wages of the lowest-paid workers, the problem, as I have said, would cease to have much economic significance. Almost everyone would be working who was able to work. The system could then be reduced further by totally denying benefits to any able-bodied person, or to anyone suffering as the result of his own irresponsibility, such as drug addicts and alcoholics. After some years, once the government had ceased to be regarded as offering anything but the most minimal relief from want, and private charity had been reestablished in the public's eyes as the place to which the indigent must turn, the remaining public welfare system could probably be totally abolished, practically without being missed.

A vital aspect of the campaign for the abolition of the welfare system must be the conversion of intellectual opinion among the groups most affected. They must understand that the system's demise is indispensable to the genuine assimilation of all groups into American society and essential to the opportunities of every person now on the welfare rolls who would like to make something of his life, and to the opportunities available to his children.

When I first wrote the above discussion of the elimination of the welfare system, I believed that the element of gradualism was necessary not only for the reasons stated but also if efforts to eliminate the system were to have any hope of gaining significant public support. On this score, it appears that I may have been wrong. For example, the state of Wisconsin now intends to remove people from the welfare rolls after two years if they turn down a job or job training, and Governor Weld of Mas-

sachusetts wants to compel welfare recipients to find work within sixty days or else lose their cash benefits or take state-provided community-service jobs.¹⁴ It remains to be seen whether such policies, which apparently give no thought to the need to abolish the obstacles presently standing in the way of employment, can not only be enacted but also be maintained in the face of the serious hardships that are likely to accompany them.

Elimination of Public Hospitals

Public hospitals and public clinics could also gradually be abolished. Their operation and the ownership of their assets could be turned over to recognized private charities, which would temporarily receive public funds to finance their operation. But the appropriation of public funds for such purposes would steadily fall, again, say, at a rate of 10 percent per year. These charity hospitals and clinics would be empowered to charge fees to their patients, at their discretion, to help compensate for the loss of government funds. It should be expected that the elimination of government control would be accompanied by major reductions in the costs of operating these hospitals and clinics. Medicaid could be phased out in step with the reduction in the public funds turned over to the now private charity hospitals and charity clinics. (Obviously, it would be extremely desirable if this process were accompanied by the most rapid possible liberalization of the licensing requirements for entry into the medical profession and for the ownership and operation of hospitals and clinics.)

Firing Government Employees and Ending Subsidies to Business

I believe that it is possible to fire government employees and abolish government subsidies to business with the support of the groups concerned. This can be accomplished by making the termination of employment or loss of subsidy to the immediate financial self-interest of the parties. What could be done is to offer very generous severance terms, in the form of the continued payment of the salary or subsidy for a limited time, during which the parties would be fully free to change over to any alternative private, unsubsidized activity they wished.

Thus, for example, a government employee presently receiving a salary of, say, \$30,000 a year and whose job deserves to be eliminated might continue to receive that salary for a full year, while being free to do anything he wished in the way of private economic activity. He would be in a position to take a substantially lower-paying job in private industry and use his severance pay to tide him over until he had gained sufficient work experience to increase his earnings to a level comparable to what they had been before. Or he could go to school and in that way

very comfortably learn the skills necessary to earn an income in private industry comparable to what he had earned as a government employee.¹⁵

In comparison with the present situation, such an arrangement would be very much in the self-interest of the general, taxpaying public. The financial burden of the taxpayers would certainly be no greater than it is now, and it would, of course, be reduced as soon as the severance pay of the government employees came to an end. Moreover, to the extent that the government employees are presently engaged in carrying out policies of destructive interference in the lives of the citizens, the public would enjoy the immediate gain of the end of some part of such interference. It is a comparatively minor evil to pay a simple dead weight subsidy to former government employees now engaged in other activities, when the alternative is to continue to support them as destroyers. Of course, in order to prevent anyone from taking unjust advantage of such a plan, government employees who received its benefits, should thereafter be barred from government employment (other than elective office) for a protracted period of time, perhaps for life—unless they refunded the extraordinary severance pay they had received.¹⁶

To the extent that the former government employees turned to seek jobs in private industry, their competition would cause the money wage rates of the average worker there to drop. This would be the case both insofar as they entered the labor market prior to the reduction in government payrolls and in taxes and insofar as, when it came, the reduction in government payrolls constituted a drop in the aggregate demand for labor. (This last would be the result to the extent that taxpayers spent the funds they no longer paid in taxes to meet government payrolls, in buying goods rather than in paying wages.¹⁷) A tendency toward a drop in wage rates would, of course, also be present as the result of the phasing out of the welfare system and of social security, inasmuch as both would bring about an increase in the supply of labor relative to the demand for labor.

As the readers of this book should know by now, the effect in all these cases would be benevolent. For the necessary fall in wage rates would be accompanied by reductions in prices that would be still greater. This is because the employment of more workers means more production and thus lower prices caused by more supply, as well as the saving of taxes to support the unemployed or unproductively employed.¹⁸ The fall in prices relative to wage rates, moreover, would be a continuing one, because the effect of reduced government spending, reduced taxation, and reduced government interference in general is increased capital accumulation and thus a rising productivity of labor. Capital accumulation and the

rise in the productivity of labor would be the result both of a greater relative production of capital goods and a higher productivity of capital goods. The greater relative production of capital goods would be made possible by reduced government spending and lower taxes and thus more saving and productive expenditure relative to consumption expenditure. The higher productivity of capital goods would be the result both of lower taxes and thus greater incentives to use capital goods efficiently, and of reduced government interference of other types that stands in the way of the efficient use of capital goods.¹⁹

It follows, and deserves to be stressed, that the long-run effect of firing unnecessary government employees is to progressively increase the economic well-being of *those employees*, along with that of everyone else, and that this is true even in the absence of any severance pay. The former government employees also benefit from the additional capital accumulation and rising productivity of labor and real wages that are made possible. They too benefit from the fact that more people now contribute to production instead of having to be supported out of the production of others, and that production is no longer held down by their activities.

Essentially the same conclusion applies to welfare recipients. In the long run, they too would be economically better off living as self-supporting wage earners in a progressing economy than as welfare recipients. Their gain would come not only from the economic progress or more rapid economic progress that abolition of the welfare system would greatly contribute to, but also, and in many cases even more importantly, from having at long last to develop and actualize their innate human potential, which the welfare system has permitted them to avoid doing. Being compelled at last to work in order to live, many of them would accept that necessity and strive to do better at it, whereas at present they need strive for nothing and thus develop into nothing.

There is absolutely no kind of magic or “free lunch” assumed here. The source of the universal gains is an increase in production. Every individual’s removal from an unproductive or destructive position in government employment or on the welfare rolls, to a positive, productive position in private employment, adds to the total of what is produced and contributes to the further increase in the total of what is produced, through making possible additional capital accumulation. It is because of this increase in total production that everyone is in a position to gain, with no one having to lose. It should actually be no more surprising that former government employees end up being economically better off without their government jobs than that blacksmiths and horse breeders end up being better off without their former jobs—and that they do so, even if they must settle for a

relatively lower position on the economic scale. Indeed, it should be less surprising when one considers that the nature of so many government workers’ jobs is precisely the stifling of innovation and improvement and that the loss of such jobs means precisely the opening of the way to progress and improvement. By the same token, the gain of former welfare recipients from the abolition of welfare should be no more surprising than the gain of someone needlessly confined to a hospital from his discharge and emergence into the world of life and action.

Every serious advocate of capitalism has always been able to understand such facts in connection with the so-called long run. The proposal I have made about generous severance pay for government employees makes it possible for a harmony of material self-interests to exist even in the very short run.

The principle of generous severance terms could be applied to the elimination of government subsidies to business, in the following way. As compensation for the abolition of a subsidy, the government would continue the payment of funds for a number of years equal to the profits and depreciation allowances that the subsidized enterprises would have earned had the subsidies been continued. Its payments could also cover the interest and other such contractual obligations the firms may be obliged to pay as the result of having reasonably entered into such arrangements in connection with the production of the subsidized item. Severance allowances would also probably have to be given for a time to the employees of those enterprises, equal to their wages or to a major portion of them. In addition, it would probably be necessary to some extent to provide such payments to the firms producing equipment or other supplies for the subsidized enterprises, and to their employees. For example, as compensation for the elimination of farm subsidies, not only farmers and their employees would have to receive severance allowances, but also the farm equipment industry and its employees. The total of the severance allowances in any given year, however, would not exceed what the government presently spends in buying the products concerned. The payments at each stage of production would not apply to the sales revenues received at that stage, but only to the much smaller figure of the net income earned by the various parties, plus depreciation allowances.

In this way, I believe that the businesses that are presently recipients of government subsidies, together with their employees and suppliers, could be given a powerful short-run interest in the abolition of their subsidies. They could be placed in a position in which the severance allowances they received would make the transition to producing for the free market virtually pain-

less, indeed, even positively rewarding insofar as those allowances plus immediate earnings in the free market exceeded the income previously derived from the government.

Escaping from Rent Control With the Support of Tenants

The rental housing market, having suffered in places such as New York City from two full generations of rent control, and with no end to rent controls in sight, has devised a method of escaping from the destructive effects of rent controls, and of doing so with the support of the tenants involved. The method rests on the recognition by landlords that in point of fact the tenants have acquired a kind of squatter's rights to the apartments they occupy, "rights" which have acquired long-standing legal sanction that almost certainly will continue to be upheld by the government. Based on this recognition, the method of escape adopted by growing numbers of landlords is that of allowing the tenants to reap a substantial share of the financial gains resulting from an apartment house becoming converted to condominium or cooperative housing. This is the meaning of the fact that landlords offer their existing tenants substantially below-market "insider prices" on the purchase of the apartments they occupy, on condition that the tenants agree to the building's change from that of rental housing to condominium or cooperative status. The tenants are then free to turn around and sell their units or rights to their units for a substantial gain, which, of course, is what wins their cooperation.

This is a very sad situation insofar as it represents the fact that to an important extent a group of nonowners has managed to acquire the status and rights of property owners by means of a government-sanctioned—indeed, government-led—violent appropriation. It is the closest the United States has thus far come to a situation comparable to that of a successful feudal invasion, in which an earlier group of property owners is forcibly dispossessed by a subsequent group of property owners. Nevertheless, it is better that property rights of the appropriators finally be recognized than that property should remain indefinitely in a condition in which no one has the power to use it well. Under rent control, tenants can stay on as long as they like, and consume the capital invested in the buildings in which they live. They are succeeded by other such tenants. The result is simply the destruction of the stock of housing, inasmuch as the rent controls deprive the landlords of the incentive and, indeed, the ability, to maintain their housing. Compared with this alternative, the conversion of rental housing to a different status, free of rent controls, at least makes possible the maintenance of the stock of housing and its possible increase.

Apart from once and for all abolishing existing rent

controls—however unlikely the prospect may be in many places at present—the contribution that the government could make to the process of the market's freeing itself from rent controls would be constitutionally to guarantee that once any property managed to escape from rent controls, it would never again, under any pretext, be subjected to them. This would eventually operate to reestablish an extensive market in rental housing. Such a market, of course, is vital for all those who cannot afford to buy their housing.

5. Abolition of Income and Inheritance Taxes

The total abolition of the personal and corporate income taxes and of the inheritance tax is an essential feature of a procapitalist political program. It is required by the individual's right to his own property. In addition, progress toward the abolition of these taxes helps to create the conditions required for economic progress, by increasing economic incentives and the ability to save, both of which serve to promote capital accumulation and thus a rising productivity of labor and rising real wages.²⁰

It must be stressed that the more rapidly economic progress can take place, thanks to reductions in the income and inheritance taxes, the more rapidly can the relative size of the government in the economic system be reduced. The consequence of this is that the degree to which people must experience the burden of the government's exactions is correspondingly diminished. If economic progress can take place at a rate of, say, 3 percent a year, then even if government activity were not reduced at all, the relative size of the government in the economic system would be cut in half in a single generation. For in that time economic progress at a 3 percent annual rate would have succeeded in doubling the size of the economic system. Thus, the burden experienced even from supporting a government of the same size would be felt much more lightly.

These facts imply two important principles pertaining to our political program. First, in reducing income tax rates, our primary emphasis should usually be on reducing the maximum rates, until there exists only a single proportional income tax rate. Reductions in the upper brackets have the greatest impact in strengthening economic incentives and saving, and thus do the most to bring about economic progress. We need to make the public aware of how everyone benefits from these tax reductions—of how they operate to raise the demand for labor and thus wages, and, at the same time, progressively to increase the productivity of labor and thus the supply of goods relative to the supply of labor, which steadily reduces prices relative to wages and thereby steadily raises real wages.²¹ Of course, once the so-called

progressive aspects of the income and inheritance taxes have been eliminated, work should immediately commence on the steady reduction in what remains of those taxes, and should continue until they are totally eliminated.

Second, a closely related minimal short-run political demand we should make is that the level of real per capita government spending be immediately frozen, so that it does not exceed its current level. Such a demand would be a call not for the immediate abolition of the welfare state and improper government activity of all kinds, but a demand for an immediate cessation in their further growth. Its implementation would result in a continuing automatic shrinkage in the relative size of the government, so long as economic progress continued.

A possible way to start on the elimination of the income/inheritance tax right now would be to fight for the immediate adoption of a universal exemption of at least 51 percent of everyone's income from federal, state, and local income taxation under all circumstances. This would be in the name of the principle that the individual is the owner of his own income. The 51 percent exemption would constitute meaningful recognition of this principle. Over the years, we would work to increase the tax exempt portion of everyone's income while reducing the rates on the taxable portion, until the income tax was totally abolished. Given the drastic reductions in welfare-type spending I have proposed and the achievement of economic progress, it should be possible to phase out the income tax entirely over the course of a generation.

The same phase-out procedure should be applied to the corporate income tax. In addition, in the short-run, we should demand the elimination of the double taxation presently entailed in the corporate income tax. It represents double taxation for a corporation first to be taxed on its income, and then for the stockholders of that corporation to be taxed again on what they receive from their own corporation, which has already paid a substantial income tax. The principle of the 51 percent exemption and its progressive enlargement should be applied to the total of every individual's personal income *plus* his share of the profits of any corporation in which he owns stock.

However, the most important short-run goal that we should emphasize in connection with taxes is compelling the government to respect the ordinary civil rights of taxpayers. We should demand the abolition of criminal penalties for income-tax evasion, in the name of the principle that an individual cannot steal or fraudulently keep what is his own property to begin with. Also, just as in the case of government agencies seeking search warrants, we should demand that the Internal Revenue Service be compelled to obtain a prior court order authorizing any seizure of property or attachment of salaries and bank accounts it wishes to undertake. If it is not

possible to obtain such elementary protection of individual rights, then a compromise that at least would be a move in the right direction would be the existence of automatic judicial review of all such IRS activities. And until criminal penalties for not paying taxes are eliminated, we should demand that the Fifth Amendment rights of individuals to remain silent in order not to incriminate themselves be applied to taxpayers, i.e., that no criminal penalties exist for failure to file an income tax return. In other words, we should demand that taxpayers, who are presently subject to criminal law, enjoy the full civil rights accorded to criminals. In answer to objections that the income tax cannot work without the violation of elementary civil rights, we should reply that if that is the case, then it is further proof of why the income tax must be abolished. So long as the supporters of the income tax wish to retain it, we must demand that they accept the burden of finding ways of harmonizing it with respect for such rights.

A further principle that I believe should be applied in connection with proposals for the reform of the income tax is that no reductions of any kind should ever be made in existing tax exemptions, shelters, or so-called loopholes. Our principle should be that no one's income taxes should ever be increased over what they would be under existing law. It is true that the various exemptions, such as for interest paid on home mortgages, have some economically distorting effects by artificially encouraging some types of economic activity at the expense of other types, but those distortions will become less and less significant with the reduction in the burden of the income tax, and will disappear altogether when it disappears. We should take the position that every reform of the income tax must serve to reduce the income taxes paid by some or all people, and not increase the income taxes paid by anyone.

Still a further principle that we must uphold concerning tax reform, and one whose necessity should be obvious on the basis of all the preceding discussions concerning the role of capital formation and the consequences of inflation, is that tax reductions must be accompanied by equivalent or even more than equivalent reductions in government spending—specifically, in *nondefense spending* primarily. In view of the highly destructive effects of budget deficits, it should be clear why tax cuts must be accompanied at least by equivalent reductions in government spending of one kind or another. Deficits, it should be recalled, deprive the economic system of the benefit of the portion of the supply of savings that must be used to finance the deficits. In the absence of a gold standard, they also lead to the rapid inflation of the money supply, which, of course, also undermines capital formation. Cutting taxes without cutting government spending,

therefore, is no solution for reducing the government's assaults on the economic system.²²

The reason the reductions in government spending must be primarily at the expense specifically of non-defense spending is that defense is one of the few legitimate functions of government. Spending for defense should be cut only as it becomes genuinely safe to do so. It should be blatantly obvious that we should never advocate imperiling the defense of this country, which means, essentially, the defense of such freedom as exists in the world, in order to preserve any aspect of the welfare state. Indeed, our need for national defense exists for no other reason than to prevent the imposition of the underlying premise of the welfare state in a more extreme and more consistent form by outside military force. That premise, of course, is that some men have the right to enslave others for the satisfaction of their needs. Thus, not only must we never dream of sacrificing national defense to any aspect of the welfare state, but what we want national defense for is precisely to protect us from the logically consistent version of the welfare state that is represented by totalitarian socialism. Furthermore, what we should advocate in connection with national defense is *overwhelming military superiority* for the United States. That is our only real guarantee of avoiding war. If we have such superiority, we will not start a war, and it is unlikely that anyone else will dare to do so.

6. Establishment of Gold as Money

The establishment of gold as money is essential to the achievement of a capitalist society. (What is said concerning gold, of course, also applies to silver.²³ Furthermore, for reasons explained in the last chapter, the gold or silver money I speak of should be understood as a 100-percent gold or silver money—i.e., a 100-percent-reserve system—in which, apart from subsidiary token coinage, all money either literally *is* gold or silver or is receipts for gold or silver that are fully backed by same.)

The establishment of gold as money on these terms is necessary in order to end inflation and all of its destructive consequences. It is necessary in order to take the power to inflate—that is, to create money virtually out of thin air—out of the hands both of the government and of the banking system operating with the sanction of the government. It is necessary in order thereby to subordinate the government to the financial power of the citizens and to make people aware of the cost of government spending, and to end the arbitrary redistribution of wealth and income, the undermining of capital accumulation, the possibility of utter economic devastation either through wage and price controls or the ultimate destruction of money, and deflation, depression, and mass unemploy-

ment. It is also necessary for making possible the rapid and radical dismantling of the welfare state, by removing the threat of depression as an accompaniment of that process.

Because I have thoroughly discussed the role of gold and the methods for achieving a gold standard in the last part of the previous chapter, I will say no more about this vital subject here. However, it had to be named here at least to this extent.

7. Procapitalist Foreign Policy

In the present-day world, a procapitalist foreign policy is indistinguishable from a pro-American foreign policy. The United States is the world's leading capitalist country. It is so on the basis of its fundamental laws—its Constitution and Bill of Rights. And, not surprisingly, it is hated for it. It is regarded by much of the rest of the world in the same way that within the United States the minority constituted by businessmen and capitalists—the “rich”—are regarded by much of the rest of the American citizenry.²⁴ If the United States is to stand up for itself, it must learn to stand up for capitalism.

The most essential point which needs to be recognized is that to the extent that the United States is a capitalist country, its government is morally legitimate, because to that extent its government acts to defend individual rights, and the powers it exercises consist of nothing more than those of the individual's delegated right of self-defense. By the same token, governments which do not recognize the existence of individual rights, governments whose very existence is based on the premise of the forcible sacrifice of the individual to the collective, have no moral legitimacy.²⁵ This means, above all, that the surviving Communist regimes, such as those of mainland China, North Korea, and Cuba, and many, if not most of the governments of the so-called third-world countries have no moral legitimacy.

The overthrow of these governments is earnestly to be desired on behalf not only of their own citizens, who are enslaved, but also on behalf of the people of the entire world, who are forcibly deprived of the benefits they could otherwise derive if these countries were free—benefits in the form of the free development of the talents of the citizens of those countries and the free development of their natural resources. A major principle here is that the violation of the rights of the individual anywhere is an attack on the well-being of people everywhere.²⁶

A foreign policy based on these principles would deal with such governments as bandits and outlaws, temporarily holding power by means of force and fear. This does not mean that it would be the obligation of the U.S. government to go to war with such countries if it were

not itself attacked or directly threatened by them. But it certainly does mean, as a minimum, that the U.S. government should do nothing to promote the existence of such governments. It should certainly not aid them in any way, nor provide them with any kind of forum in which to defend their crimes, nor denounce those who prevent them from expanding their power or who prevent similar regimes from coming to power in the first place.

As examples from the recent past, the U.S. government should certainly not have provided Soviet Russia or Communist Poland with free food or loan guarantees. Instead, it should have allowed them to suffer the famines that socialism causes, while at the same time explaining to the world how socialism was the cause of the famines and thus how millions were forced into starvation because of the power-lust of the Communist rulers and their insistence on the preservation of the socialist system. It should have led world opinion in demanding that the Communist rulers step down and the socialist system they had imposed be abolished, so that the citizens of the Communist countries could become free to produce and live. Had the United States followed this policy, the collapse of communism would have occurred decades earlier.

Today, the United States should withdraw all official recognition from the remaining Communist-bloc countries and from totalitarian third-world countries, such as Iran, Iraq, and Libya, and expel their diplomats and alleged trade missions. It should end all so-called cultural exchanges with such regimes. If necessary, it should withdraw from the United Nations and expel that organization from U.S. territory. The only purpose served by the presence of these individuals and institutions is spying, terrorism, and subversion. If the governments of these countries wish to continue to be recognized, the prime condition must be their formal disavowal of socialism and the adoption of a genuine plan for the protection of individual rights and the establishment of capitalism in their countries.

It should be recalled that the very fact of the United States adopting a policy of laissez faire and respect for private property rights at home would itself go a long way toward undermining the power of today's leading terrorist governments, namely, those of the Middle East. At the same time, it would cut the ground from under the resurgence of religious fanaticism in the region, which, like the arms build-up by governments in the region, is financed by money derived from an artificially high price of oil. These results would follow because a leading consequence of the adoption of a policy of laissez faire and respect for private property rights by the United States would be a great increase in the supply of domes-

tically produced oil and other sources of energy, which latter, as substitutes for oil, would cause a reduction in the demand for oil. In the face both of a substantial increase in the supply and reduction in the demand for oil, there would be a sharp decline in its price.²⁷ Thus, the revenues that finance the terrorists and fanatics would sharply decline.

A major obstacle to the pursuit of a proper foreign policy by the U.S. government is the incredible corruption of thought which exists not only within the United States but, to a much greater degree, in the rest of the world. This corruption was blatantly evident in the fact that throughout the so-called cold war, the state of world opinion was such that the expulsion of Communist diplomats from the United States would have been regarded as an act of aggression on our part. A call for the Communist leaders to step down and end the enslavement of their citizens would have been regarded as a transgression against their allegedly God-given right to enslave—or, as it is customarily put, “an interference in the internal affairs of sovereign nations.”

The ability of the United States to pursue a proper foreign policy and the ability of foreign countries themselves to move toward the achievement of a capitalist society depends on the spread of procapitalist ideas abroad. To say the same thing in different words, both our immediate national security and our long-run goal of the establishment of a fully capitalist society throughout the world, with worldwide free trade, freedom of investment, and freedom of migration, require that we be interested in the spread of proreason philosophy and procapitalist economic theory in foreign countries as well as in the United States.

A major task in the years ahead must be to bring about the translation of all of our main books into all of the world's major languages. *Human Action*, *Socialism*, *Atlas Shrugged*, and about fifty or more other titles, should be made available in Russian, Polish, and Chinese, as well as in Japanese, Korean, Arabic, and all the other leading languages. Efforts should be made to promote the circulation of these books everywhere. I do not agree for a moment with the notion that only people brought up in the United States or Canada can readily appreciate our literature. Our philosophy recognizes only one reality and one human nature. No matter what intellectual and psychological obstacles a particular culture may create in the thinking of people, there is always some significant number who are open to new ideas. Our commitment to our philosophy and our national and economic self-interest require that we try to reach these people. As an example of the importance of doing so, just imagine the effect on our national self-interest of a totalitarian re-

gime's someday having to deal with people who have come to realize that each individual possesses reason and has an inalienable right to life, and that their reason and their lives are being sacrificed because of nothing more than the rulers' willful refusal to abandon an irrational dogma. Imagine the effect of the regime's being infiltrated by such people.

It should go without saying that all such intellectual efforts must be undertaken privately, not as an activity of the U.S. government.

As a further point in connection with what we should be working toward in the area of foreign policy, I would like to make a suggestion for another special campaign. This would be a campaign urging newspapers, magazines, and television stations which choose to maintain officially accredited reporters in Communist or other totalitarian countries to provide a warning label on all their reports from those countries which are obtained with government sanction. The label would identify the totalitarian nature of the country and state that no reason exists for regarding the report as anything but propaganda serving the interests of the government that originated it or sanctioned it.

Freedom of Immigration

We need to make a beginning toward the establishment of freedom of immigration. A logical place to begin would be in calling for free immigration from our immediate neighbors, Canada and Mexico. There is not the slightest reason for excluding Canadians. They are virtually indistinguishable from Americans, and had one or two battles gone the other way early in our history, would in fact be Americans. By the same token, had the Confederacy won the Civil War, then, with the prevalence of today's ideas, present-day New Yorkers would probably not be able to migrate to Texas, nor Texans to California. Such restrictions, based on mere accidents of history, simply have no logical foundation.

It should not be necessary to add that the free immigration of Canadians, Mexicans, or any other nationality should not be at the expense of the immigration allowed under existing law to the members of any other nationality. As in the case of tax reduction, no one should be made any worse off than he now is, because of an attempt to improve conditions for anyone else.

The reason we must seek to abolish restrictions on Mexican immigration at the earliest possible moment is because the attempt to restrict it is in danger of making us adopt some of the most obnoxious features of the former South African regime—namely, a virtual pass law, in which people of Latin origin will have to carry identity papers to show on demand to immigration

police, who, if they do not find the appropriate "papers," will have the authority to destroy the lives of said individuals by uprooting them from their jobs and homes and deporting them. Already virtually Gestapo-like conditions exist in Southern California in connection with a notorious immigration checkpoint, where fleeing Mexicans of all ages and both sexes have often run into oncoming automobile traffic rather than be arrested by officers of the Immigration and Naturalization Service. This ignominy, I must note, has now been compounded by the recent passage of Proposition 187 in the state of California, which, if upheld in the courts, will actually impose the requirement of having an official identity card that must be shown on demand to the authorities.

Furthermore, the principle of private property rights implies that the Mexicans, and everyone else, have a perfect right to come here—to work for anyone who is willing to hire them and to live wherever anyone is willing to sell or rent to them. The violation of the rights the Mexicans or any other category of immigrant is a violation of the private property rights of employers and landlords—it is telling them that other people have the right to dictate whom they may or may not employ or to whom they may or may not sell or rent their property. It is a blatant manifestation of collectivism to believe that somehow the people of the United States as a whole have the right to tell the individual, private owners of property how they may use their property—that they must use it not as they, the private owners wish to use it, but as the nation collectively, or at least a majority of those voting, wish it to be used.

As I explained in Chapter 9, in a capitalist society free immigration does not deprive those already present of the opportunity of working and it does not reduce their standard of living. On the contrary, in the long run free immigration into a capitalist society from a semifeudal one, such as Mexico's, must operate to raise the general standard of living in the capitalist society, because it means that more human beings will now live under freedom and have the opportunity to develop their talents.²⁸ There are Mexicans and the children of Mexicans who have the potential for making the same kind of economic contribution to the general standard of living as have immigrants from other countries before them.

The only legitimate argument against unrestricted Mexican immigration (or unrestricted immigration of any other ethnic group) is based on the existence of our welfare state. To the extent that Mexicans come here and go on welfare and Medicaid, or use public hospitals and public schools, and place an increased burden on government-subsidized public transportation facilities and so forth, then, it is true, there is a genuine loss imposed on the people already here. The solution, however, is not to

violate the right of the Mexicans to immigrate, but to start dismantling our welfare state.

Without immediately abolishing the totality of the welfare state, which would be politically impossible, we could simply change its terms and make all noncitizens ineligible for its programs. This, of course, is essentially what a portion of California's Proposition 187 seeks to do. However, that proposition also seeks to expel the immigrants and to deter further immigration through fear. Totally unlike Proposition 187, the mere exclusion of the immigrants from the welfare state would not impose any actual burden or disability on them. It would not be they who had to carry identity papers and prove why they should not be deported. There would be no question of that. On the contrary, it would only be the American citizens who sought the alleged benefits of the welfare state who would have to show papers and prove their citizenship.

While excluding the immigrants from the welfare state, we should simultaneously remove all government-imposed barriers to their being supplied privately with what they need. This would entail the removal of government licensing requirements in connection with meeting the medical, educational, transportation, and sanitation needs of the immigrants. As far as possible, this should be accompanied by privatization of such things as existing government-owned hospitals, schools, bus lines, and garbage-collection operations. An important result of privatization would be that the presence of the larger numbers of people resulting from immigration would be viewed as a source of more business, not more problems, as it is under the ineptitude of government ownership. In addition, in order to reduce the injustice that would exist in making immigrants pay taxes for the support of the welfare state for the native population, the immigrants should receive as nontaxable wages what would otherwise be their own and their employer's social security and Medicare contributions made in connection with their employment. The ironic effect of all these liberalizing measures would be to give the immigrants more freedom than today's American citizens, and in that sense to make them truer Americans than today's American citizens. If, at the same time, the immigrants could be reached with procapitalist ideas, this might well serve as the foundation for their being developed into a major group opposed to the welfare state for anyone.

In the present circumstances, it is especially important to make every effort to exclude immigrants from the public education system. At one time, it is true, public elementary education succeeded in educating pupils of all different nationalities in the three R's. And even though its own existence represented a contradiction of the principle of individual rights, it instilled in pupils a

basic respect and admiration for the United States. Today, public education teaches very little to anyone. It turns out masses of illiterates and students who have not the slightest idea of what the United States stands for. One of the last things we should want is today's public education system teaching masses of immigrants in their own language. One of the major subjects that would be taught would undoubtedly be revolutionary Marxist nationalism. Under such conditions, as far fetched as it may sound, large-scale Mexican immigration into the Southwest could well result, one or two generations later, in a widespread demand for the return of the Southwest to Mexico. Thus, an important part of any campaign for free immigration for Mexicans should be an attack on public education and its Marxist domination. It is vital that the immigrants be assimilated as English speakers who support capitalism.

It would be enormously valuable if it could be explained to the immigrants that only the philosophy of individualism and respect for private property rights made possible their immigration. It would be legitimate to require of all immigrants an oath swearing to uphold the system of private property rights and to educate their children in the English language.

It would be a very short step from freedom of immigration for Mexicans to freedom of immigration for everyone.

Friendly Relations With Japan and Western Europe

Because of their exceptional economic strength and thus their potential someday to constitute a serious military threat to the United States, a cardinal principal of American foreign policy must be the maintenance of friendly relations with Japan and the countries of Western Europe. To assure this, what is necessary on our part is a policy of free trade, freedom of investment, and freedom of immigration—in short, a policy of full capitalism with respect to these countries. If we were to follow this policy, we would eliminate any possible economic basis of aggression against us on the part of these countries.²⁹ And for all of the reasons shown in this book, from an economic point of view we could only gain from such a policy—probably very substantially. As I have shown, we would gain even if we alone were to follow a policy of free trade while the others clung to various protectionist measures. In that case our position would be analogous to the situation of a territory in which inbound transportation costs were lower than outbound transportation costs.³⁰

If we followed such a policy toward these countries, we could reasonably ask them to undertake a larger share of the defense of the free world, in accordance with the increase in wealth and income they have experienced.

We would not have to worry that in doing so, we were encouraging potential enemies to arm, as we should presently be concerned.

Of course, the policy of full capitalism with respect to foreign relations should be applied to all countries. However, for the reasons stated, it is especially important in these two cases.

8. Separation of State from Education, Science, and Religion

Finally, it is necessary to turn to the subject of separation of state from education, science, and religion.

Abolition of Public Education

The system of public education could be abolished over the course of a generation, in a way that need not impose financial hardship on the parents of any child alive at the time of the abolition's commencement. The method would be the enactment of state laws declaring that as of the end of the seventh school year following the enactment of the law, that state and its localities will no longer be responsible for the financing of the first-grade education of any student; that a year after that, they will no longer be responsible for the financing of the second-grade education of any student; and so on, through all the elementary, secondary, and college grades. This procedure would enable the parents of children alive at the time of the enactment of the phase-out legislation to go on using the public education system if they wished; it would give prospective new parents a year's notice that they would be responsible for the cost of their children's education.

The abolition of public education should be preceded by the recognition of the right of parents to educate their own children and by the abolition of educational licensing requirements. It would also be proper if the public schools were to be made to begin charging tuition fees to those who could afford them, which would be progressively increased, until they reflected the public school system's costs. The fee system would permit steadily increasing competition and growth on the part of private schools, which would then be in a position easily and totally to displace the public schools.

One of the most immediate points to fight for in connection with the abolition of public education is the abolition of the federal Department of Education and all federal aid to education. These measures would create an immediate improvement in education by eliminating a major layer of bureaucracy and by forcing the elimination of unnecessary courses and unsound educational methods that are fostered, if not mandated, by the availability of federal funds. They would thus bring about a

renewed concentration on the three R's and other serious subjects.

In the struggle against public education, an important principle to stress is that the public education system is inherently unsuited to teach any subject about which there is controversy. This is because teaching such a subject necessarily entails forcing at least some taxpayers to violate their convictions, by providing funds for the dissemination of ideas which they consider to be false and possibly vicious. On the basis of this principle, the public schools should be barred from teaching not only religion, but also history, economics, civics, and biology. In the nature of things, only private schools, for whose services people have the choice of paying or not paying, can teach these subjects without violating the freedom of conscience. The fact that barring the public schools from teaching these subjects would leave them with very little to teach, and place them in a position in which they may as well not exist, simply confirms the fact that public education should be abolished.

Separation of Government and Science

The above principle concerning the government's violation of the freedom of conscience in supporting the promulgation of controversial ideas also constitutes an argument for the abolition of practically all government support of the arts and sciences. There is great controversy concerning the artistic merit of various schools of literature, painting, and sculpture. There is significant and growing controversy even over the various theories of natural science, such as the controversy between the supporters of the "Big-Bang" theory of the origin of the universe and the supporters of the steady-state theory of the universe, which holds that the universe did not have an origin. For the government to finance any artistic or scientific activity means to compel taxpayers who hold the activity to be artistically or scientifically worthless, and perhaps immoral as well, to finance it nonetheless.

More fundamentally, our opposition to government involvement in art and science—and in education—is based on Ayn Rand's principle that force and mind are opposites.³¹ Matters of truth and value can be determined only by the voluntary assent of the human mind. Yet government is essentially a policeman with a gun and club. It settles matters by means of force. This is directly contrary to the nature of knowledge. It has no place in the laboratory, the lecture hall, or the art gallery. The determination of what is true or false, or possessing or lacking in value, simply cannot properly be decided by government officials. Nor can it properly be decided by majorities in voting booths. Such a thing is further contrary to the nature of knowledge, which always begins as the discovery of just one mind, and which is as yet totally

unknown to the entire rest of the human race. Governments and majorities must not be allowed to crush the isolated individual, who is the source of all new knowledge and improvement. Yet precisely this is the outcome of government support of science and art, which scoops up the limited funds available for the support of such activities and arbitrarily dictates how they are to be spent.

As to the tactics to be used to remove the government from these areas, the most important is the continuous demonstration of the contrary nature of government force, on the one side, and knowledge and value freely assented to, on the other.

An important step in reducing and ultimately eliminating government interference in science would be to require that all alleged scientific studies financed in any way by any government agency or department prominently state that fact. This might be required in the form of an amendment to the Freedom of Information Act. The requirement should extend to all press releases and public announcements made by the government or any of its employees concerning the study. In this way, the study could be easily identified as coming from the government or associated with the government. The requirement would serve, in effect, as a warning label. In addition, all information relevant to the study's being undertaken, including the initial application for a government grant, and all correspondence and internal government documents pertaining to the study, should be identified in an appendix to the study, and copies made readily available to any member of the public wishing to see them. The study should also be required to include an appendix providing an intelligible explanation of the methodology on which it was based. These requirements would make it possible to scrutinize and judge the scientific seriousness of such studies far more easily than is possible today, and thus to enable people much more readily to distinguish government propaganda from science.

An important first step in the eventual abolition of such agencies as the Food and Drug Administration (FDA) and the Environmental Protection Agency (EPA) would be a law severely limiting their powers to ban drugs and chemical substances. The law would nullify the power of the agency's adverse ruling in any case in which similar agencies in, say, two or more modern foreign countries, such as Canada, Switzerland, and Great Britain, have found no reason to ban a substance. In other words, it would subject these agencies to a form of liberalizing "peer review." In such cases, in order to ban a substance, the FDA and EPA would have to prove their case before a court of law. The principle that the FDA and EPA and their staffs are not endowed with any form of divine guidance could be progressively extended—to

the point where any *one private individual* was free to act on his contrary opinion. (After all, why should the opinions of American citizens be viewed as inferior to those of foreign bureaucrats?)

Perhaps the best way ultimately to abolish the FDA and the EPA would be to demand their conversion to private agencies, having no powers of compulsion and supported exclusively by private funds. They would then operate as advisory agencies, in competition with other such private advisory agencies, free to pronounce whatever opinions they wished about any subject, but not free to have force used to back their opinions—except when they could go before a court of law, as any other private citizen, and *prove* the existence of a danger to the lives or property of parties not willing to take the risk of such danger.

Separation of State and Church

Our opposition to government involvement in religion is based on the same foundation as our opposition to government involvement in education and science. Indeed, government-sponsored religion represents the most naked kind of use of force against the mind. Religion is based on faith. The use of force to impose it or its values is always the use of force in order to compel acceptance of what cannot be proved or denial of what can be proved.

The supporters of capitalism must take the lead in the battle against the current incursions of religion into politics and government. Nothing could be more vital to progress toward the establishment of a capitalist society. The old stereotypes of the advocates of socialism as enlightened liberals and the advocates of capitalism as religious conservatives need to be decisively broken. From now on, in accordance with the actual facts, the advocates of capitalism must be viewed as the representatives of enlightenment, and the socialists as the representatives of irrationalism and the Dark Ages.

In the 1930s and 1940s, to be sure, the seemingly enlightened Left was able to depict its opponents as virtual Ma and Pa Kettles, living on a farm somewhere, totally cut off from modern civilization, and projecting utter ignorance and contempt for science and technology. Exactly that image is what the New Left has chosen to wrap itself in, ever since it joined the ecology movement. We should be sure that the public eventually understands this fact and that it is with the New Left that those who place faith above reason belong.

Previous discussion in this book and in Ayn Rand's *The New Left: The Anti-Industrial Revolution* provide the essential basis for the transformation of the view of which side wears the mantle of Reason. They clearly show how the ecology movement, which is the last gasp

of the Left, is thoroughly riddled with irrationalism and hostility to science and technology.³² Furthermore, the whole of this book and all of the writings of von Mises, of the other Austrian and classical economists, and of Ayn Rand, show beyond a shadow of a doubt that capitalism in no sense whatever depends on the acceptance of any form of faith or denial of reason. The case for capitalism is thoroughly rational.

In view of the fact that socialism has demonstrated its failure and that as a result its advocates have largely given up the banner of reason, means that the success of a rational, capitalist political program should be all the more rapid. By the admission of both sides, capitalism is the only system to which advocates of reason can turn.

Furthermore, the projection of a rational, capitalist political program, actually capable of solving major national and world problems, will stand as a major philosophic affirmation of the power of the human mind. Thus, it can be an important source of gaining recruits for all aspects of a rational philosophy. As previously shown in connection with the ecology movement, the cultural surge in blatant irrationality that has taken place in recent decades is due in no small measure to the demonstrated failure of socialism as a politico-economic system. Socialism is what most intellectuals have regarded as the system called for by logic and reason. As a result, its failure has served to shake their confidence in reason, and thus to open the floodgates to irrationalism.³³ By the same token, a resurrection of respect for the potential of reason in the politico-economic realm will promote the case for reason everywhere.

The advocates of capitalism should take the lead in the defense of the freedoms of press and speech. At the same time that we seek to protect it for purveyors of "prurient" literature, we should seek to protect it for the writers of financial newsletters, whom the SEC wants to censor; for corporations, whom the Congress and the Federal Elections Commission want to censor by denying them the right to support political candidates of their choice; for unpopular speakers whom student thugs want to censor by denying them the ability to be heard by their audience; for ordinary citizens whom the Department of Housing and Urban Development wants to censor for speaking out against government-sponsored projects in their neighborhoods. We should demand the freedoms of speech and press for all advertisers, including cigarette advertisers.

We should place the establishment of full freedom of the press and of the more recent forms of communication, such as movies, radio, and television, in the forefront of our fight for a capitalist society. Long before the establishment of a fully capitalist society, we should seek the

establishment of a fully free press and media as the pattern for all other industries later to follow. We should demand their exemption from all government regulation immediately—that is, we should demand that these industries, because of the intellectual nature of their products and services, be freed at once from the income tax, the antitrust laws, the labor laws, and every other form of government regulation and interference, so that they may advance their ideas totally without fear of punitive action of any kind being taken against them.

9. A General Campaign at the Local Level

The seven preceding sections have described various major aspects of the campaign for capitalism. Here it is appropriate to bring some of those aspects together in the form of a specific program that, over the course of less than a decade, would bring about the economic and cultural revival of America's leading city, New York. I choose to focus on New York not only because it is the country's leading city, but also because, of any major American city, it best represents the destructive economic and social consequences of contemporary American "liberalism," of which it is the intellectual home.

What would be required to restore New York to its former prosperity and greatness would be the combination of the elimination of public welfare, the abolition of rent controls, and the privatization of the city's transportation system.

The abolition of welfare, of course, would have to be preceded by the elimination of minimum-wage and pro-union legislation and of restrictions on child labor over the age of fourteen. In the absence of the outright repeal of minimum-wage and pro-union legislation at the national level, it would be necessary for the city to obtain a special congressional exemption from that legislation. These preliminary measures would be necessary so that, as I have said before, the present welfare recipients would have a realistic opportunity of finding employment. As I have also said before, the elimination of welfare would need to take place gradually, say, over a ten-year period.³⁴ The elimination of public welfare and restrictions on employment would make possible a radical improvement in the lives of the poorest portion of the city's population, whose members would then live by working and recognize their responsibility for their own well-being, and who thus could advance to far higher economic levels than could ever be possible for them while on the welfare rolls. At the same time, and for much the same reasons, it would make an enormous contribution to the reduction in crime and thus to the improvement of the lives of the rest of the city's population, if large numbers of those who otherwise would have been

out committing crimes—namely, unemployed, impoverished juveniles and the hardened criminals they grow up to become—were instead busy earning money by working.

The abolition of rent control, of course, would radically and progressively improve the city's housing stock. It would also bring about the return of the middle class to the city.³⁵ Another important consequence of the repeal of rent control would be a great increase in the revenues of the city government that were derived from property taxes.³⁶ Property tax collections would soar by virtue of bringing the value of all the housing and land in the city that is presently under rent controls, up to the free-market level. The great increase in property-tax revenues, combined with the elimination of expenditures for welfare, would make possible the elimination of much or even all of the city's income and sales taxes, which would further improve the quality of life in the city and promote the return of industry and commerce. As a result of the vast increase in the property-tax base, even the property-tax rate could probably eventually be reduced.

The privatization not only of the city's subway system but also of its bus lines, accompanied by the phasing out of restrictive taxicab licensing requirements, would achieve major improvement in the city's transportation system. This too would represent an important improvement in the daily life of the average New Yorker and serve to encourage the return of industry and commerce to the city.

No doubt, repeal of victimless crimes legislation and the consequent ability of the city's police department and judicial system to concentrate all of their resources on apprehending and punishing those guilty of crimes against the persons or property of others would be a further measure vital in restoring the life of the city.

Needless to say, success in enacting the above program in New York City would operate powerfully to promote the cause of capitalism in the entire country.

10. The Outlook for the Future

Every supporter of capitalism should take heart. All across the world, socialism is now in visible retreat and outright collapse. Its supporters are in a state of intellectual disintegration, turning en masse against science, technology, and reason, as they magnify the evidence of their own intellectual incompetence into a distrust of the human intellect as such. Having for generations pompously proclaimed the possibility of their rationally planning every detail of human life—at the point of a gun and at the price of everyone else's planning and self-interest—and somehow thereby achieving a utopia, they now

begin to see the devastation they have caused, and, their dream in ruins, they sink to the level of superstitious primitives, living in fear of the intellect and of its products science and technology. In a word, they have become "environmentalists." Safety to them now appears to lie in whatever is not man-made—in whatever is "natural," viz., tested by millions of years of blind evolution.³⁷

In these circumstances, even though the world may appear to be continuing to rush on, irresistibly, to a new Dark Age, surprisingly little is needed to bring about the most radical reversal of the political currents. Just one or two victories won in the name of explicit procapitalist principle is all that is required. One or two such victories would prove that there were no irresistible currents of doom. They would serve to galvanize large numbers of people to further action, in the knowledge that rational efforts in the realm of political action actually work.

At the moment, a promising candidate for such a reversal of the currents is the defeat of efforts to establish socialized medicine in the United States, by means of showing that the actual solution for the problem of soaring medical costs is the elimination of government intervention into medicine and the corresponding widening of the zone of economic freedom in medicine. All of the necessary intellectual ammunition is present to do this—that is, all of the objective facts and logical arguments are on the side of the supporters of capitalism.³⁸ At the same time, with the collapse of socialism across the world, the advocates of socialized medicine have completely lost their intellectual base. Objectively, they are men without logical arguments and without an intellectual home. They are riding on nothing but inertia. On the basis of the fundamentals of the situation, there is no doubt but that they can be stopped.

Perhaps the supporters of capitalism are still too few and for the most part still insufficiently prepared intellectually to win this battle. If so, there will be numerous future occasions on which they can turn the tide. They have only to learn how to articulate their case—that is, to become intellectuals who thoroughly understand economic theory and political philosophy, and enough of more fundamental philosophy to uphold the value of human reason. If enough of them do this, their cause will be irresistible. It will be as the waves of the ocean acting on a foundation made of sand. Inevitably and irresistibly the sand is washed away and the foundation undermined. "Sand" is all that remains of the intellectual foundations of socialism and the opposition to capitalism. Let the advocates of capitalism proceed in the knowledge not only that socialism is dead, but also that what the world still needs to learn is why capitalism deserves to live.

Notes

1. See above, pp. 19–21.
2. Along these lines, see also below, pp. 987–988.
3. On these last points, see above, pp. 286–290 and 316–317. See also above, p. 668.
4. On the nature of the process of capital accumulation and economic progress, see above, pp. 622–636, especially p. 627.
5. At the same time, of course, it should be explained how the fall in wage rates that the freedom of competition would cause in the face of unemployment, would tend not to lower but to raise real wage rates. On this point, see above, pp. 584–585.
6. See above, pp. 384–385, which explain why government intervention is a leading cause of homelessness. See also above, pp. 202–203.
7. For a full discussion of the government’s responsibility for the crisis in medical care, and how a free market in medical care would solve all aspects of the problem, see George Reisman, *The Real Right to Medical Care Versus Socialized Medicine* (Laguna Hills, Calif.: The Jefferson School of Philosophy, Economics, and Psychology, 1994.)
8. For an example of an appropriate compromise concerning the Food and Drug Administration, see below, p. 987.
9. On this point, see above, pp. 655–660.
10. Strictly speaking, individuals are presently eligible to receive social security retirement benefits beginning at age 62. This should be eliminated with the rise in the minimum eligibility age to 70.
11. I estimate this to be the case on the basis of data available from the U.S. government. See, for example, U.S. Department of Health and Human Services, Social Security Administration, *Social Security Bulletin Annual Statistical Supplement 1989*, p. 163.
12. A number of states are already making efforts to deny additional aid to mothers who give birth to children while on the welfare rolls. See *Los Angeles Times*, April 30, 1994, p. A14.
13. It is implicit in previous analysis in this book that the abolition of prounion legislation along with minimum-wage legislation, would make possible the employment of unskilled workers with a lesser fall in wage rates than would be the case without the abolition of prounion legislation. On this point, see above, pp. 659–660.
14. See *New York Times*, national ed., January 14, 1994, p. A12.
15. A kindred policy is already being practiced to some extent by the federal government in the form of job “buyouts.” Under this arrangement, the government pays an individual up to \$25,000 to retire early. See *Washington Post*, October 28, 1993, p. A21; *ibid.*, August 22, 1994, p. D2.
16. Under the present program of job buyouts, the period of disqualification for new government employment appears to be only two years. See *ibid.*, October 28, 1993, p. A 21.
17. On the subject of taxes and the demand for labor, see above, pp. 648–650.
18. See above, pp. 584–585. See also above, pp. 648–650.
19. See above, pp. 634–636.
20. See above, pp. 622–642.
21. See above, pp. 308–310 and 622–642.
22. For elaboration of this point, see above, pp. 829–831.
23. Concerning the necessity of using silver as money, see above, pp. 958–959.
24. I am indebted to von Mises for this observation, which he made on occasion in his seminar.
25. Cf. Ayn Rand, “Collectivized Rights,” in Ayn Rand, *The Virtue of Selfishness* (New York: New American Library, 1964) pp. 135–143. Cf. also, the U.S. Declaration of Independence.
26. See above, pp. 322–323 and 362–363.
27. See above, pp. 234–237.
28. On this subject, see above, pp. 362–363. See also above, pp. 634–636.
29. See above, pp. 322–323 and 351–354.
30. See above, the discussions of unilateral free trade on pp. 190–191 and 535–536.
31. Cf. Ayn Rand, *Atlas Shrugged* (New York: Random House, 1957) pp. 1023–1024.

BIBLIOGRAPHY

A BIBLIOGRAPHY OF WRITINGS IN DEFENSE OF CAPITALISM

The following is a list of books and essays ranging from essential to helpful to the defense of capitalism.

1. LUDWIG VON MISES

Von Mises is by far the most important defender of capitalism in the realm of economic theory. A thorough knowledge of his writings is essential. I list his four major treatises first, and then, for the most part, his more popular works. The best way to approach the treatises is not to begin on page one, but to start with whatever chapters or sections appear to be of special interest, and then, later on, read the remaining portions.

Human Action, 3d ed. rev. Chicago: Henry Regnery Company, 1966. (The works of von Mises and those of many other authors on this list are available from The Foundation for Economic Education, Irvington-on-Hudson, New York.)

Socialism. London: Jonathan Cape, 1969. Reprint. Indianapolis: Liberty Classics, The Liberty Fund, 1982.

The Theory of Money and Credit. New Haven: Yale University Press, 1953. Reprint. Irvington-on-Hudson, New York: Foundation for Economic Education, 1971. Reprint. Indianapolis: Liberty Classics, The Liberty Fund, 1981.

Theory and History. New Haven: Yale University Press, 1956. Reprint. New Rochelle, New York: Arlington House, 1969.

Planning For Freedom, 4th ed. enl. Grove City, Pennsylvania: Libertarian Press, 1980.

Bureaucracy. New Haven: Yale University Press, 1944. Reprint. Grove City, Pennsylvania: Libertarian Press, 1993.

Omnipotent Government. New Haven: Yale University Press, 1944. Reprint. Grove City, Pennsylvania: Libertarian Press, 1993.

The Free and Prosperous Commonwealth. New York: D. Van Nostrand Company, 1962. (This book has also been reprinted under the title *Liberalism: A Socio-Economic Exposition*. Irvington-on-Hudson, New York: Foundation for Economic Education, 1995.)

The Anti-Capitalistic Mentality. New York: D. Van Nostrand, 1956. Reprint. Grove City, Pennsylvania: Libertarian Press, 1994.

The Historical Setting of the Austrian School of Economics. New Rochelle, New York: Arlington House, 1969. Reprint. Auburn, Alabama: Ludwig von Mises Institute, 1984.

Economic Freedom and Interventionism: An Anthology of Articles and Essays. Edited by Bettina Bien Greaves. Irvington-on-Hudson, New York: Foundation for Economic Education, 1990.

The Ultimate Foundation of Economic Science. New York: D. Van Nostrand Company, 1962.

Epistemological Problems of Economics. Translated by George Reisman. New York: D. Van Nostrand Company, 1960.

A Critique of Interventionism. New Rochelle, New York: Arlington House, 1977.

Nation, State, and Economy. New York: New York University Press, 1983.

Economic Policy. South Bend, Indiana: Regnery/Gateway, 1979.

On the Manipulation of Money and Credit. Dobbs Ferry, New York: Free Market Books, 1978.

Money, Method, and the Market Process: A Collection of Essays. Norwell, Massachusetts: Kluwer Academic Publishers, 1990. Despite the fact that the book's editor and publisher allowed it to go to press with a distracting number of typographical errors, the essays it contains are all of great value and eminently worth reading.

Notes and Recollections. Grove City, Pennsylvania: Libertarian Press, 1978.

A worthwhile book to have available while reading *Human Action* is *Mises Made Easier, A Glossary*. Compiled by Percy Greaves, Jr. Dobbs Ferry, New York: Free Market Books, 1974.

2. AYN RAND

The writings of Ayn Rand provide numerous powerful arguments on behalf of capitalism. I list her works in the order that I believe is best suited for coming to a clear and cohesive understanding of them. (Most of these works, incidentally, are available in paperback editions by Signet.)

Atlas Shrugged. New York: Random House, 1957. Reprint. New York: Dutton, 1992.

For the New Intellectual. New York: Random House, 1961. This book contains the philosophical speeches from all of Ayn Rand's novels.

The Virtue of Selfishness. New York: New American Library, 1964.

Capitalism: The Unknown Ideal. New York: New American Library, 1965.

The New Left: The Anti-Industrial Revolution, rev. enl. ed. New York: Penguin USA, Meridian, 1993.

Philosophy: Who Needs It. Indianapolis and New York: Bobbs-Merrill Company, 1982.

The Voice of Reason. New York: New American Library, 1988.

Introduction to Objectivist Epistemology, 2d ed. enl. New York: NAL Books, 1990.

The Fountainhead. New York: The Bobbs-Merrill Company, 1943. Reprint. New York: Macmillan Publishing Co., 1986.

We The Living. New York: Random House, 1959. Reprint. New York: Penguin Books, 1995.

Anthem. Caldwell, Idaho: The Caxton Printers, 1953. Reprint. New York: Penguin Books, 1995.

3. THE ECONOMIC WRITINGS OF HENRY HAZLITT

Hazlitt is perhaps the greatest popularizer of economics of all time. I regard the first two of the following works as classics.

Economics in One Lesson, new ed. New York: Arlington House, 1979. Reprint. New York: Crown Publishers, 1979.

The Great Idea. New York: 1951. Reprinted, with an important change of the ending, under the title *Time Will Run Back*. New Rochelle, New York: Arlington House, 1966.

The Failure of the "New" Economics. New York: D. Van Nostrand, 1959.

The Man Versus the Welfare State. New Rochelle, New York: Arlington House, 1969.

The Conquest of Poverty. New Rochelle, New York: Arlington House, 1973.

Editor, Andrew Dickson White, *Fiat Money Inflation in France*. Irvington-on-Hudson, New York: Foundation for Economic Education, 1960.

Editor, *The Critics of Keynesian Economics*. New York: D. Van Nostrand Company, 1960.

4. THE EARLY AUSTRIAN SCHOOL: MENGER AND BÖHM-BAWERK

Carl Menger, *Principles of Economics*. Glencoe, Illinois: The Free Press, 1950. Reprint. Grove City, Pennsylvania: Libertarian Press, 1994.

Eugen von Böhm-Bawerk, *Capital and Interest*. 3 vols., Sennholz and Huncke translation. Spring Mills, Pennsylvania: Libertarian Press, 1959. (Libertarian Press is currently located in Grove City, Pennsylvania.)

Shorter Classics of Böhm-Bawerk. Spring Mills, Pennsylvania: Libertarian Press, 1962.

5. THE BRITISH CLASSICAL SCHOOL

An indispensable part of any serious study of procapitalist economic theory is a thorough, first-hand knowledge of the British Classical economists, i.e., the school principally comprising Adam Smith, David Ricardo, James Mill, John R. McCulloch, John Stuart Mill, and John E. Cairnes. The ideas of these men dominated educated opinion on economic matters in the Western World in the century following 1776 (the date of the publication of *The Wealth of Nations* as well as of the American Revolution). This was the period in history most closely approximating laissez-faire capitalism, and the Classical economists deserve much of the credit for it.

As I showed in Chapter 11, the writings of the Classical economists contain a number of gross errors, disastrous formulations, and major contradictions. Nevertheless, many of the fundamental principles set

forth in their writings are correct and constitute an essential contribution to economic theory. As I also showed in Chapter 11, when properly understood, their ideas, far from being the foundation of Marxism, as is generally believed, provide the basis for the most powerful refutation of Marxism, as well as lay the foundation for powerful critiques of Keynesianism and the pure-and-perfect and imperfect-competition doctrines. Much of the present book is a testimony to the importance of their work, indeed, to the fact that their ideas are an essential part of the core around which economic science must be built.

In order to understand the Classical economists, it is necessary to read all of the Classical authors I have named, not just one or two. This entails a certain amount of repetition, but the repetition will serve to cement one's understanding. The two main Classical economists are Smith and Ricardo. Ricardo, however, is especially difficult. I suggest, therefore, reading McCulloch and the two Mills before Ricardo, or giving Ricardo a second try after reading these authors.

Adam Smith, *The Wealth of Nations*. London, 1776. Reprint of Cannan edition. Chicago: University of Chicago Press, 2 vols. in 1, 1976.

David Ricardo, *Principles of Political Economy and Taxation*, 3d ed. London: 1821. This work has been reprinted as vol. I of *The Works and Correspondence of David Ricardo*. Edited by Piero Sraffa. Cambridge: Cambridge University Press, 1962. The full Works and Correspondence contains eleven volumes and contains all of Ricardo's writings, speeches, and correspondence with James Mill and McCulloch. Its publication spans the years 1952–1973. I recommend it highly.

James Mill Selected Economic Writings. Edited by Donald Winch. Chicago: University of Chicago Press, 1966. This volume contains both *Commerce Defended* (London: 1808) and *Elements of Political Economy*, 3d ed. rev. (London: 1844). James Mill is usually greatly underrated. As I have said, he should be credited with the best and clearest exposition of "Say's Law" extant—i.e., the demonstration of the impossibility of a general overproduction. His ideas on saving and capital are equally brilliant.

John R. McCulloch, *Principles of Political Economy*, 5th ed. London: 1864. Reprinted, New York: Augustus M. Kelley, 1965. This is probably the simplest and best overall introduction to Classical economics available.

John Stuart Mill, *Principles of Political Economy*, Ashley edition, 1909. Reprint. New York: Augustus M. Kelley, 1961. (I recommend Mill with mixed feelings because of his sympathy for socialism. Nevertheless, his writings on capital, demand, value and cost, and the overproduction doctrine are brilliant. These appear in Chapters III–VI of Book I and Chapters I–VI and Chapter XIV of Book III.)

John Stuart Mill, *Essays on Some Unsettled Questions of Political Economy*, 2d ed. London: 1874. Reprint. New York: Augustus M. Kelley, 1968.

John E. Cairnes, *Some Leading Principles of Political Economy Newly Expounded*. London: 1874. Reprint. New York: Augustus M. Kelley, 1967.

Offshoots of the British Classical School

Jean-Baptiste Say, *A Treatise on Political Economy*, 1st American Edition. Philadelphia: 1821. Reprint. New York: Augustus M. Kelley, 1971. (This was the most popular economics textbook in the United States in the decades prior to the Civil War.)

Nassau Senior, *An Outline of the Science of Political Economy*. London: 1836. Reprint. New York: Augustus M. Kelley.

Nassau Senior, *Selected Writings on Economics, A Volume of Pamphlets 1827–1852*. New York: Augustus M. Kelley, 1966.

Frederic Bastiat, *Economic Sophisms*. Translated from the French and edited by Arthur Goddard. Introduction by Henry Hazlitt. New York: D. Van Nostrand, 1964. Reprint. Irvington-on-Hudson, New York: Foundation for Economic Education.

Frederic Bastiat, *Selected Essays on Political Economy*. Translated from the French by Seymour Cain. Edited by George B. de Huszar. Introduction by F. A. Hayek. New York: D. Van Nostrand, 1964. (This volume contains the justly famous essay “The Law,” which demonstrates the inherently immoral nature of government intervention.) Reprint. Irvington-on-Hudson, New York: Foundation for Economic Education.

Frederic Bastiat, *Economic Harmonies*. Translated from the French by W. Hayden Boyers. Edited by George B. de Huszar. Introduction by Dean Russell. New York: D. Van Nostrand, 1964. Reprint. Irvington-on-Hudson, New York: Foundation for Economic Education.

Charles Holt Carroll, *Organization of Debt into Currency*. Edited with an Introduction by Edward C. Simmons. New York: D. Van Nostrand, 1964. This is a brilliant series of essays written between 1855 and 1879 showing how a fractional reserve monetary system causes depressions. Argues forcefully for a 100-percent-reserve gold standard.

6. RECENT OR CONTEMPORARY WRITINGS IN DEFENSE OF VARIOUS ASPECTS OF CAPITALISM

I apologize for the fact that the following list cannot be exhaustive and thus necessarily must omit some authors who, arguably, deserve to be included, and perhaps also omits some deserving titles by authors who have been included.

This category, it must be noted, includes authors who, while defending various important aspects of capitalism, hold grossly inconsistent positions. As explained in the Introduction to this book, this is obviously true of Hayek, Friedman, and Rothbard, for example. It can be safely left to the intelligent reader to detect such further cases of inconsistency on his own.

F. A. Hayek

The Road to Serfdom. Chicago: 1944. Reprint. Chicago: University of Chicago Press. Phoenix Books.

Capitalism and the Historians. Chicago: University of Chicago Press, 1954.

Prices and Production. London: George Routledge & Sons, 1931.

Profits, Interest, and Investment. London: George Routledge & Sons, 1939.

The Pure Theory of Capital. Chicago: University of Chicago Press, 1941.

Individualism and Economic Order. Chicago: University of Chicago Press, 1948.

Monetary Theory and the Trade Cycle. Translated from the German by N. Kaldor. New York: 1933. Reprint. New York: Augustus M. Kelley, 1966.

Editor, *Collectivist Economic Planning: Critical Studies on the Possibility of Socialism*. London: George Routledge & Sons, 1935. Reprint. New York: Augustus M. Kelley, 1975.

Milton Friedman

The Balance of Payments: Free Versus Fixed Exchange Rates. Coauthor Robert V. Roosa. Washington, D. C. American Enterprise Institute, 1967.

Capitalism and Freedom. Chicago: University of Chicago Press, 1962.

Free to Choose. Coauthor Rose Friedman. New York: Harcourt Brace Jovanovich, 1980.

The Great Contraction 1929–1933. Coauthor Anna Jacobson Schwartz. Princeton: Princeton University Press, 1965.

A Monetary History of the United States, 1867–1960. Coauthor Anna Jacobson Schwartz. Princeton: Princeton University Press, 1963.

James Buchanan

The Bases of Collective Action. New York: General Learning Press, 1971.

The Consequences of Mr. Keynes: An Analysis of the Misuse of Economic Theory for Political Profiteering, with Proposals for Constitutional Disciplines. Coauthors Richard E. Wagner and John Burton. London: Institute of Economic Affairs, 1978.

Cost and Choice: An Inquiry in Economic Theory. Chicago: 1969. Reprint. University of Chicago Press, 1978.

The Demand and Supply of Public Goods. Chicago: Rand McNally, 1968.

Democracy in Deficit: The Political Legacy of Lord Keynes. Coauthor Richard E. Wagner. New York: Academic Press, 1977.

William H. Hutt

The Economics of the Colour Bar: A Study of the Economic Origins and Consequences of Racial Segregation

in South Africa. London: A. Deutsch, 1964.

The Keynesian Episode: A Reassessment. Indianapolis: Liberty Press, 1979.

Keynesianism—Retrospect and Prospect: A Critical Re-statement of Basic Economic Principles. Chicago: Henry Regnery, 1963.

Politically Impossible—?: An Essay on the Supposed Electoral Obstacles Impeding the Translation of Economic Analysis into Policy. London: Institute of Economic Affairs, 1971.

The Strike-Threat System: The Economic Consequences of Collective Bargaining. New Rochelle, New York: Arlington House: 1973.

The Theory of Collective Bargaining: A History, Analysis, and Criticism. Glencoe, Illinois: 1954. Reprint. San Francisco: Cato Institute, 1980.

The Theory of Idle Resources, 2d ed. Indianapolis: Liberty Press, 1977.

Israel Kirzner

An Essay on Capital. New York: Augustus M. Kelley, 1966.

Competition and Entrepreneurship. Chicago: University of Chicago Press, 1973.

The Economic Point of View. New York: D. Van Nostrand, 1960.

Market Theory and the Price System. New York: D. Van Nostrand, 1963.

Perception, Opportunity, and Profit. Chicago: University of Chicago Press, 1979.

Murray Rothbard

America's Great Depression. New York: D. Van Nostrand, 1963.

For a New Liberty. New York: Macmillan, 1973.

Man, Economy, and State: A Treatise on Economic Principles, 2 vols. New York: D. Van Nostrand, 1962. This book should definitely *not* be used as a substitute for von Mises's *Human Action*, all claims and recommendations to the contrary notwithstanding.

What Has Government Done to Our Money? Novato, California: Libertarian Publishers, 1978. This booklet is a brilliantly clear analysis of government intervention into money, which, uncharacteristically, is not marred by any major contradictions on the author's part.

Hans Sennholz

Age of Inflation. Belmont, Massachusetts: 1979. Reprint. Grove City, Pennsylvania: Libertarian Press.

Death and Taxes. Washington, D. C.: Heritage Foundation, 1976. Reprint. Grove City, Pennsylvania: Libertarian Press.

Debts and Deficits. Grove City, Pennsylvania: Libertarian Press.

The Politics of Unemployment. Grove City, Pennsylvania: Libertarian Press, 1987.

Mark Skousen

Economics on Trial: Lies, Myths, and Realities. Homewood, Illinois: Business One Irwin, 1991.

The 100% Gold Standard: Economics of a Pure Money Commodity. Washington, D. C.: University Press of America, 1977.

The Structure of Production. New York: New York University Press, 1990.

Bernard Siegan

Government, Regulation, and the Economy. Lexington, Massachusetts: Lexington Books, 1980.

Economic Liberties and the Constitution. Chicago: University of Chicago Press, 1980.

Land Use Without Zoning. Lexington, Massachusetts: Lexington Books, 1972.

Other People's Property. Lexington, Massachusetts: Lexington Books, 1976.

The Supreme Court's Constitution: An Inquiry into Judicial Review and Its Impact on Society. New Brunswick, New Jersey: Transaction Books, 1987.

Thomas Sowell

The Economics and Politics of Race: An International Perspective. New York: Morrow, 1983.

Markets and Minorities. New York: Basic Books, 1981.

Race and Economics. New York: D. McKay, 1975.

Walter Williams

America, A Minority Viewpoint. Stanford, California: Hoover Institution Press, 1982.

Black America and Organized Labor: A Fair Deal? Coauthors Loren Smith and Wendell Gunn. Washington, D. C.: Lincoln Institute for Research and Education, 1979.

South Africa's War Against Capitalism. New York: Praeger, 1989.

The State Against Blacks. New York: New Press, 1982.

Youth and Minority Unemployment. Stanford, California: Hoover Institution Press, 1977.

Pamphlets by George Reisman

Capitalism: The Cure for Racism. Laguna Hills, California: The Jefferson School of Philosophy, Economics, and Psychology, 1992. An explanation of how capitalism and the unhampered profit motive achieve equal pay for equal work and operate against all aspects of racial prejudice in the marketplace, and how the unjust treatment of blacks in contemporary American society is the result of the mixed economy, not of capitalism.

Education and the Racist Road to Barbarism. Laguna Hills, California: The Jefferson School of Philosophy,

Economics, and Psychology, 1992. An explanation of the nature and universal value of Western civilization, and why the efforts to replace its teaching with “Afro-centric” and “Latino-centric” studies are based on racism and imply the destruction of education.

The Real Right to Medical Care Versus Socialized Medicine. Laguna Hills, California: The Jefferson School of Philosophy, Economics, and Psychology, 1994. This 44-page pamphlet upholds the rational right to buy all the medical care one wishes from willing providers. It shows how the displacement of this right by the pseudo-right to medical care based on need has created all aspects of the medical crisis. The pamphlet shows not only how a free market in medical care would solve the medical crisis and make medical care progressively better and more affordable, but also what specific steps need to be taken to achieve such a free market. It is full of powerful intellectual ammunition designed to enable the advocates of individual rights and economic freedom to take the offensive on this vital issue.

George Reisman is also the author of *The Government Against the Economy*. Ottawa, Illinois: Jameson Books, 1979. As noted elsewhere, this book is incorporated in the present volume as Chapters 6–8.

7. BASIC PROCAPITALIST READINGS IN POLITICAL PHILOSOPHY

John Locke, *Second Treatise on Civil Government*. Many editions. The basic political documents of the United States should be read in conjunction with Locke—i.e., *The Declaration of Independence* and *The Constitution*.

Wilhelm von Humboldt, *On the Sphere and Duties of Government*. London, 1854.

Herbert Spencer, *The Man Versus the State*. Caldwell, Idaho: The Caxton Printers, 1969.

On this subject, see also, above, Ayn Rand, *The Virtue of Selfishness* and *Capitalism: The Unknown Ideal*.

8. READINGS ON SELECTED SUBJECTS

(Note: the introductory paragraphs of Section 6 of this bibliography apply here.)

Advertising

Jerry Kirkpatrick, *In Defense of Advertising*. Westport, Connecticut: Quorum Books, 1994.

Yale Brozen, ed., *Advertising and Society*. New York: New York University Press, 1974.

The Ecology Movement

Jay Lehr, ed., *Rational Readings on Environmental Concerns*. New York: Van Nostrand Reinhold, 1992. (This volume includes George Reisman, “The Toxicity of Environmentalism” as its summary chapter.)

Dixie Lee Ray and Lou Guzzo, *Trashing the Planet: How Science Can Help Us Deal with Acid Rain, Depletion of the Ozone, and Nuclear Waste (Among Other Things)*. Washington, D. C., Regnery/Gateway, 1990.

On this subject, see also, above, Ayn Rand, *The New Left: The Anti-Industrial Revolution*.

Aspects of Government Intervention

E. C. Pasour, Jr., *Agriculture and the State*, Oakland, California: The Independent Institute, 1995.

William Mitchell and Randy Simmons, *Beyond Politics*. Boulder, Colorado: Westview Press for The Independent Institute, 1994.

Tibor Machan, *Private Rights & Public Illusions*. New Brunswick, New Jersey: Transaction Publishers for the Independent Institute, 1995.

John W. Sommer, ed., *The Academy in Crisis*. New Brunswick, New Jersey: Transaction Publishers for the Independent Institute, 1995.

Richard Vedder and Lowell Gallaway, *Out of Work*. New York: Holmes & Meier for The Independent Institute, 1993.

The Monopoly Myth

D. T. Armentano, *Antitrust and Monopoly*. Oakland, California: The Independent Institute, 1996.

Yale Brozen, *Is Government the Source of Monopoly? and Other Essays*. San Francisco: Cato Institute, 1980.

Wayne A. Leeman, “The Limitations of Local Price Cutting as a Barrier to Entry,” *Journal of Political Economy*, August 1956.

John S. McGee, “Predatory Price Cutting: The Standard Oil (N. J.) Case,” *The Journal of Law and Economics*, Vol. 1, October 1958.

Soviet Russia

Robert G. Kaiser, *Russia*. New York: Atheneum, 1976.

Hedrick Smith, *The Russians*. New York: Quadrangle Books, 1976.

Anatoly Marchenko, *My Testimony*. New York: Dutton, 1969.

G. Warren Nutter, *The Strange World of Ivan Ivanov*. New York: The World Publishing Company, 1969.

Paul Craig Roberts, *Alienation and the Soviet Economy*. New York: Holmes & Meier for the Independent Institute, 1990.

9. NEOCLASSICAL ECONOMICS

Some of the following works, especially those of Jevons, are valuable, though badly mixed. Others are so badly muddled as to be worthless, despite their great reputations. In any case, an expert knowledge of economics requires familiarity with them.

William Stanley Jevons, *Theory of Political Economy*, 4th ed. London: Macmillan and Co., 1924. The book represents an original discovery of the law of diminishing marginal utility, but is an overreaction to the labor theory of value held by the classical economists. It claims Ricardo “shunted economics onto the wrong track.”

William Stanley Jevons, *The State in Relation to Labour*. London: Macmillan, 1882. This book is philosophically corrupt. It openly abandons the principle of laissez faire and attacks arguments based on abstract principles of rights. It is nevertheless valuable for a devastating analysis of labor unions.

Léon Walras, *Elements of Pure Economics*. New York: Augustus M. Kelley, 1969. Originally published in French in 1874, this book is famous for an original discovery of the law of diminishing marginal utility roughly coinciding with its discovery by Menger and Jevons. However, it is one of the early works of mathematical economics, and thus helped to set the stage for severing economic theory from reality by introducing the needless complications of higher mathematics.

Philip H. Wickstead, *The Common Sense of Political Economy*, rev. enl. ed., 2 vols. London: 1933. Reprint. New York: Augustus M. Kelley, 1967.

Alfred Marshall, *Principles of Economics*. 8th ed. New York: The Macmillan Company, 1920. An extremely diffuse, confused book, which, among other things, helped to set the stage for the theory of "pure and perfect competition" that I criticized in Chapter 10. Marshall was the teacher of Keynes.

John Bates Clark, *The Distribution of Wealth*. New York, Macmillan, 1938. This book contains the original exposition of the theory of diminishing marginal productivity, which it propounds far more cogently than today's textbooks. Nevertheless, the basic argument is weak and its exposure is used to discredit capitalism.

Frank H. Knight, *Risk, Uncertainty, and Profit*. Boston, 1921. This work is another major source of the pure and perfect competition doctrine.

Irving Fisher, *The Rate of Interest*. New York, 1907, and *The Theory of Interest*. Reprint. New York: Augustus M. Kelley, 1954. Fisher advances a host of wrong or confused ideas about profit and interest that helped to pave the way for Keynes.

10. THE ENEMIES OF CAPITALISM

I include this group because an advocate of capitalism should have a first hand knowledge of the ideas of its enemies.

Karl Marx, *The Communist Manifesto*. Chicago: Henry Regnery Co., 1954.

Karl Marx, *Das Kapital*. vol. I, New York: The Modern Library, 1937.

J.M. Keynes, *The General Theory of Employment Interest and Money*. New York, Harcourt Brace, 1936.

Joan Robinson, *The Economics of Imperfect Competition*. London: Macmillan and Co., 1933.

Edward Chamberlin, *Theory of Monopolistic Competi-*

tion, 6th ed. Cambridge, Massachusetts: Harvard University Press, 1950. This is a second source of the oligopoly/monopolistic-competition doctrine.

Benjamin E. Lippencott, ed., *On the Economic Theory of Socialism*. Minneapolis: University of Minnesota Press, 1938. Contains the attempts of Lange and Taylor to overturn von Mises's proof that economic calculation under socialism is impossible.

John Kenneth Galbraith, *The Affluent Society*. Boston: Houghton Mifflin. 1958. This book is included only because of its popularity and Galbraith's continuing influence. It is one of the least intellectually significant attacks on capitalism I know of. See my review, "Galbraith's Modern Brand of Prussian Feudalism," *Human Events*, February 2, 1961.

John Kenneth Galbraith, *The New Industrial State*, 2d ed. rev. New York: New American Library, 1971.

Joseph P. McKenna, *Aggregate Economic Analysis*, 5th ed. Hinsdale, Illinois: Dryden Press, 1977. A comparatively clear exposition of the essential ideas of Keynes. The first or second edition is the most preferable because of greater simplicity in comparison with later editions.

Paul Samuelson and William Nordhaus, *Economics*. 13th ed. or previous editions. Englewood-Cliffs, New Jersey: McGraw-Hill, 1989. This is the leading "text-book case" of the exposition of economic fallacies and anticapitalist doctrines.

Dudley Dillard, *Economic Development of the North Atlantic Community*. Englewood Cliffs, New Jersey: Prentice-Hall, 1967. If there is any fallacy that Samuelson has managed to avoid, it can probably be found in this book.

A FURTHER WORD ON READINGS

My list has omitted the names of such eminent economists as Wicksell Fetter, Edgeworth, and Pareto, and men of even greater stature, such as Adam Smith's predecessors Quesnay, Dupont, and Turgot, i.e., the French Physiocrats. The interested student will come across many references to these men as he reads the works I have recommended.

For the purpose of rounding out one's knowledge as soon as possible, it pays to read a history of economic thought early on. I recommend the one I found most helpful, and which I used shortly after beginning my own study of economics. It is:

Frank A. Neff, *Economic Doctrines*, 2d ed. New York: McGraw-Hill Book Company, 1950.

The best way to learn the history of economic thought in depth, however, is to read the great economists themselves on their predecessors, for example, Adam Smith on the Physiocrats and the Mercantilists, in *The Wealth of Nations*.

- Capital goods, 131, 445–456, 622–642
 - advances in, set stage for further advances in, 65
 - classification as, not based on physical characteristics, 445–446
 - common confusions about, 450–456
 - defined, 132, 445
 - demand for
 - can radically and permanently exceed the demand for consumers’ goods, 843–856; luggage set analogy, 850–851
 - consumers’ goods, vs., determines relative production of, 622–626, 809–820
 - depends on saving and productive expenditure, 622–629, 632–634, 682–689, 694–696; and on private ownership of the means of production and respect for property rights as foundations thereof, 19–20, 58, 139, 280, 300–303, 306–310, 622–641, 642, 644, 651–654, 743–744, 826–829
 - dynamic effects of changes in relative, and production of, 625–628, 809–820
 - fall in the demand for, as source of rise in the demand for labor reduces real wage rates while raising nominal wage rates, 647–648
 - importance of recognizing the separate, for the theory of capital accumulation 709–715
 - increases in relative, and production of, beyond maintenance proportion serve to accelerate the rate of capital accumulation, 627–628, 809–820
 - increase in relative, and production of, could be accompanied decelerated acceleration of accumulation of, 629
 - reduced by government budget deficits, 638, 829–831, 927–928
 - reduced by progressive personal income and inheritance, corporate income, and capital gains taxes to finance government spending, 306–310, 636–639, 826–829, 931–933
 - reduced by social security, 22–23, 37(23), 638
 - reduced (relative to consumers’

- goods) by inflation, 930–935, 936–937
- rise in, even when the cause of a fall in demand for labor, ends up raising real wage rates, 639–640
- rise in, at expense of fall in demand for consumers' goods: the cross-hatching of production, 854–856
- internally produced, 447–448
- maintenance proportion of, 132–133, 627, 638–640
- defined, 623
- lower, the, the greater is the degree of economic freedom and respect for property rights, 635
- permanently reduced by virtue of operation of uniformity-of-profit principle, 635
- reduced by freedom of immigration into a capitalist society, 634–635
- See also* Freedom of immigration, refutation of the decline-in-capital-goods-per-capita argument
- reduced by population growth in division-of-labor society, 634–635
- See also* Population growth, beneficial economic effects of
- reduced by rise in productivity of capital goods, 132–133, 634–635
- rendered impossibly high by socialism, 277–278, 641
- rendered unnecessarily high by government intervention, 637, 650, 653
- rises in absence of technological progress, 629
- See also*, below, Capital goods, productivity of
- output in proportion to supply of, 626
- production of, in relation to maintenance proportion determines whether economy is stationary, progressive, or retrogressive, 623
- production with growing supply of, raises productivity of labor, 132, 622–642
- production with, represents indirect, more time-consuming process of production in comparison to production without, 133
- productive consumption of, requires fresh production of, to offset, 132, 623
- productivity of, 622, 628–631, 634–636
- defined, 629
- increased by economic freedom and respect for property rights, 634–636
- maintained by technological progress, 628–629
- reduced by government intervention, 637; *see also* Government intervention, undermines capital accumulation and real wage rates via reducing relative demand for and production of capital goods and productivity of capital goods
- rendered impossibly low by socialism, 277–278, 641
- relationship to capital, 132, 447–450
- saving of, through more efficient use increases supply of, 778
- scarcity of, 55–58, 556–557, 750–762, 779–784, 786–787, 839, 856–859
- supply of
- determined by economic degree of capitalism and productivity of capital goods, 622–642
 - determines productivity of labor, 132, 622–642
 - increased by anything that increases production in general, above all, economic freedom and respect for property rights, 634–636
 - increases in, serve to increase ability to produce capital goods and thus to make possible further increases in supply of, 278, 625–628, 632, 809–814
 - Ricardo's insights concerning increase in, 3, 634, 819–820
 - uses for, always far exceed supply of, 56–58, 556–557
- See also* Capital; Capital accumulation; Capital intensiveness; Capital value; Consumers' goods; Capitalism, economic degree of; Productive expenditure; Saving(s)

Demand

aggregate

- Consumptionist curve depicting, 545
- falling supply is the by-product of rapid increases in, 899
- formula for quantity of money and, 503
- population growth shown to be a source of rising, in real terms only insofar as contributes to more production and supply, 553
- Productionist curve depicting, 546
- products, for, and for factors of production, ratio of, between stages, 851–852
- role of net consumption in causing excess of, for products over demand for factors of production, 570, 725–744
- role of saving and productive expenditure in, 682–708
- saving as the source of increasing, in both monetary and real terms, 698
- unit elasticity of, 158

as an amount of expenditure, 152

as will combined with power of purchasing, 152, 559

change in, according to contemporary concept of, coincides with change in, according to classical concept of, 154

change in, differs from change in quantity demanded, 153, 879–880

changes in, causes of, 160–161

circularity of contemporary economics' concept of, 169

- how overcome by classical economics' concept of demand together with law of diminishing marginal utility, 169

classical concept of, applies at level of economy as a whole, where determination of, is by quantity of money, 155

contemporary, Austrian concept of, applies at level of individual industries, 155

elasticity of, 158–161, 408–423

- application of concept of, to effects of machinery on employment, 160
- defined, 158
- division into categories of elastic, inelastic, and unit elastic, 158
- examples of, 158–159

law of

- based on: income effect, 157; substitution effect, 156; law of diminishing marginal utility, which operates in and through substitution and income effects and otherwise, 156–158
- follows at level of economic system as a whole from limitless need and desire for wealth and fact that lower price expands buying power of any given expenditure of money, 156
- follows at level of individual industry from change in relative price of what the industry supplies, 156–157
 - seeming exceptions to, 161–162
 - statement of, 155–156

monetary, increases in

- caused by increases in quantity of money, 503–506
- increase prices but not real, 560

monetary and real, 559–561

real, 152, 559–561

- increased by increases in production and supply, which are necessary and sufficient to create, 559–561
- increases in quantity of money and volume of spending are neither sufficient nor necessary to create, 560

schedules or curves, 152–153

- cannot be derived from observations of price and quantity, 169
- causes of changes in, 160–161

See also Capital goods, demand for; Labor, demand for; Demand and supply; "Demand for commodities is not demand for labor"; Demand for A is the demand for A; Demand for money for holding; Money, quantity theory of; Price system, free-market; Supply

Demand and supply

- Austrian concept of supply same as in classical economics, 154
- Austrian view holds determination of price by, reduces to determination by valuations of marginal pair of buyers alone, 154
- change in, in contemporary economics means movement of schedule or curve, 153
- classical and contemporary concepts agree on direction of price changes caused by changes in, 154
- meaning of, 152–155
 - classical economics, in, 152
 - contemporary economics, in, 152
- price determination by
 - contemporary economics, in, means price determined at intersection point of curves depicting, 153
- underlie cost of production and prices determined by cost of production, 168, 201

- Energy crisis
 abundance of energy in nature, 63
 free economy, in, not possible because of
 limitless potential of natural resources
 and freedom of motivated human intel-
 ligence to act, 63–66, 176–180
 gasoline shortage would have been im-
 possible in absence of price controls,
 203–204
 misleading reports about
 blaming shortage on hoarding, 224
 campaign against the profits of the oil
 companies and blaming the oil com-
 panies for the oil shortage, 231–237
 claim that large stocks of oil proved
 oil shortage artificially created by
 oil companies, 192–194
 claim that private firms control
 prices, 238
 claim that producers withheld sup-
 plies to “get their price,” 223–226
 claim that world is running out of
 energy supplies, 63–67
 conspiracy theory of shortages, 237–238
 natural gas crisis of 1977 caused by price
 controls, 222–223
 political causation of, 66–67
 how the U.S. government and the
 ecology movement, not the oil
 companies, caused the oil shortage,
 234–237
 price controls caused, by being re-
 sponsible for: chaos in the alloca-
 tion of crude oil among its various
 products, 245–246; chaos in the
 distribution of gasoline among ge-
 ographical markets, 244–245; chaos
 in the personal distribution of
 oil products such as gasoline, 243–
 244; making it more worthwhile to
 leave oil in the ground than extract
 it, 225–228; raising the price re-
 ceived by OPEC, 254–255; the ad-
 ministrative chaos connected with
 “old” oil and “new” oil, 243; the
 hoarding of oil products, 246–247
 why the Arab oil embargo would not
 have been a threat to a free econ-
 omy: *See* Arab oil embargo
 rebuttal of the charge that the oil shortages
 of the 1970’s were “manufactured” by
 the oil companies, 192–194
 repeal of price controls enlarges supply of
 energy, 182–183

 critique of doctrine of, on land rent, 310–316
 Georgists, 12(17)
 German historical school, 6
 Germany
 following hyperinflation in, a new mark was introduced based on convertibility to dollars, 950
 unlikely to be able to provide basis for a new dollar, if dollar destroyed by hyperinflation, 950
 post–World War II prosperity of, not based on wartime destruction of, but on pursuit of sound economic policies since the war, 551
 See also Nazi Germany
 “Global warming,” 87–90
 acid rain and destruction of the ozone layer, along with, takes the place of exploitation, monopoly, and depressions as reasons for violating individual liberty, 102
 capitalism needed to cope with, if comes, 88–90
 collectivist bias of environmentalism present in treatment of, 91–93
 potential benefits of, 89
 shares honors with ecology movement's fear of new ice age as result of process of industrial development, 78, 80, 87
 weather forecast, as, 88
 See also Ecology movement (environmentalism)
- ## Gold
- clauses and prospective inflation of paper as the cause of deflation in gold, 940–941
 freedom for, as guarantee against the destruction of money, 951–954
 inflation, vs., 895–966 (especially 951–963)
 is standard money under a gold standard, 512
 money
 demand for holding of, greater and velocity of, less than that of paper, 956
 how came to be, 506–508
 is, chosen by the free market, 951
 not an invariable money, 536
 prevents inflation and policy of government budget deficits, 924–925
 renders government budget deficits deflationary, 889, 922
 rise in velocity of circulation of, unlikely to be accompanied by fall in purchasing power of, 518
 undermining of, by government intervention, 508–510
 outflow of, (or other) reserves caused by inflation, 533–535
 proper, policy for the government, a, 951–954
 remonetization of
 unilateral, by United States might attract a disproportionate share of world's gold stock, 962
 would result spontaneously if, possessed freedom of competition, 510–511, 930, 951–953
- ## Gold standard
- 100-percent-reserve
 applicable only to currency and checking deposits, not savings deposits, 514
 case for, 954–959
 falling prices under, would not be deflationary, 954–955
 liquidity, and the dismantling of the welfare state, 962–963
 means of ending inflation without a depression, 959–963
 moral virtue of, 957–958
 principle of, the, 514–515
 represents guarantee against deflation, 519, 955–956
 secure against inflation, 504, 519, 895–966 *passim*
 solution to the boom-bust cycle, 955–956
 fractional-reserve, 514, 591
 attempts to violate law of excluded middle, 957–958
 case for outlawing, 957–958

- contradiction in case for, 954–955
 subject to boom-bust cycle, 513–514, 594, 938–941
- rise in taxation of profits under, serves to reduce rate of increase in money supply and thus to limit destructive effects of the rise, 828–829
- secure against inflation, 504, 519
- undermining and loss of, in United States, 508–510

- Marginal cost**
 failure to charge price equal to, is basis of claim that economic system lacks price competition, 434–436
 implications of having to charge price equal to, 432–434
 meaning and alleged significance of price equalling, 426–430
 treatment of fixed costs when price must equal, 428–430
See also Pure-and-perfect-competition doctrine
- Marginal productivity of capital**, 557–558, 778, 787–792
 in special sense, underlies net investment when exceeds rate of profit, 756–757
See also Technological progress
- Marginal-productivity theory of wages**, 666–668
- Marginal-revenue doctrine**, 408–423
- Marginal units**, poorer buyers regularly outbid richer buyers for, 204–205, 213
- Marginal utility**, law of diminishing applications of
 determination of consumer spending patterns, 52–53; but use of mathematics here is misleading, 53
 determination of price by cost, 52, 168, 206–209, 414–416, 667
 determination of relative prices of goods and services in limited supply, 201–214
 helps explain sharp increase in price of oil as result of supply restrictions caused by U.S. government, 235
 overcomes circularity of contemporary economics' concept of demand, 169
 resolution of the value paradox of classical economics, 3, 51–52
 Say's Law and, 53–54, 568
- Böhm-Bawerk's frontiersman example of**, 49–51
 applied to illustrate determination of value by cost, 52
 determined by the least important among the most important wants that the supply of a good suffices to serve, 50
 "most important of our wants that a good is capable of satisfying" must be understood as a variable range, 49, 208
 determines the utility of each of the units of the supply, 50
 distinguishes neoclassical and Austrian economics from classical economics, 2, 3
 foundations of
 increasing satisfaction of wants, 49
 logic of choice, 49
 limitless need and desire for wealth, consistent with, 49–51
 misuse of, in attacking economic inequality, 332–335
 price sandwiching and, 155
 provides no basis for upward sloping supply curves, 162–163
 because typically not operative in valuations of sellers in a division-of-labor economy, 154, 162–163
 rebuttal to Galbraith's mistaken inference that, implies increasing wealth makes the pursuit of wealth is progressively less important, 50–51
 statement of, 49
 underlies law of demand, 155–158
 via income effect, which operates in accordance with, 157
 via substitution effect, which is special case of, 157
 answers seeming exception to, by showing that increase in quantity demanded requires drop in price sufficient to place marginal utility of the price below marginal utility of further units, 161
See also Price system, free-market
- Market economy**
See Capitalism

 confusions of, 7
 ideas of, led to monopoly doctrine and Keynesianism, 7–8
 representative-firm doctrine of, 7, 436
See also Externalities doctrine, critique of; Partial-equilibrium doctrine; Pure-and-perfect-competition doctrine
- Marx, Karl**, xli, xlii, xlviii, il
 critique of his claim that division of labor causes alienation and narrowness, 129–130
 denunciations of capitalists by, deserved by rulers of socialist society, 277
 intensification of labor and cheapening the worker's diet, on, to increase the rate of exploitation, 613
 "market socialism" a break with his doctrines, 279
 quotation(s) from
 claiming capitalists appropriate surplus labor time from women and children, with machinery to blame, 612
 claiming lengthening of the working day to maximum possible limit, 612
 claiming profits ("surplus value") made by underpayment (exploitation) of labor, 608–610
 claiming progressive impoverishment of masses, 611
 claiming tendency toward ever increasing economic concentration under capitalism, 392
 claiming value of labor itself is determined by quantity of labor required to produce it, i.e., its minimum subsistence, 607–608, and that wages are cut as the result of a fall in the price of necessities, 610
 describing capital as vampire-like, 611
 describing falling rate of profit with given rate of exploitation, hence tendency for rate of exploitation to rise, 611–612
 describing formula for rate of exploitation in terms of cotton-mill example, 608–609
 propounding his distorted, absolutist version of the labor theory of value, 605, and its implication that all value added is the result of the addition of fresh labor, 606
See also Marxian exploitation theory; Marxism; Socialism
- Marxian exploitation theory**, 473–498, 603–672
 classical-based critique, a, of conceptual framework of, 475–486
 confirmed by net consumption theory, 735–736
 framework, accepted by previous critics of the theory, 484–485
 distortions, major, of classical economics in labor theory of value, 604–607; implications for value added and income formation, 605–607
 "iron law of wages," 607–610
 falling rate of profit alleged by, as cause of rising rate of exploitation, 611
 formulas of, for
 rate of exploitation, 608–610
 simple and capitalistic circulation, 478–479
 influence of, in interpretation of modern economic history and in political agenda of contemporary "liberals," 603–604, 613
 implications of, 610–613
 appropriation of the labor of women and children, 612
 gains of capitalist the same as gains of a slave owner, 610
 lengthening of the working day, 611–612
 no gains to wage earners from economic progress, 610
 progressive impoverishment of the masses, 611
 productivity theory of wages overthrows, 613–663
 irrelevance of worker need and employer greed to determination of wage rates, 613–618
 labor and social legislation in light of, 653–663
 modern economic history in light of, 642–646
 real wages determined by productivity of labor, 618–622, which depends on capital accumulation and its causes, 622–641

- motive
 dependence on private ownership of the means of production, 137–138, 267–269, 279–282
 foundation, as, of price system and rational economic planning, 137–138, 172–218, 267–269, 279–282
 gives consumers the power to determine the relative size of the various industries, 174, 275
 keeps the various branches of industry in proper balance, 173–174, 275
 makes businessmen act as agents of the consumers, 174–175, 275–276
 operates contrary to doctrine of planned obsolescence, 214–216
 promotes safety, 79, 174–176, 642–644, 645
 represents pursuit of material self-interest under division of labor and money, 27
 underlies connection between prices and costs of production, 200–201
 underlies continuous economic progress, 176–179, 275, 635
 underlies free market's allocation principles, 201–214
 underlies uniformity-of-price principles, 187–199
 underlies uniformity-of-profit principle, 172–187
- original and primary form of income

- See, below, this main entry, primacy of permanent inequalities in rate of, 185–187*
 primacy of, 478–480
 production for, is production for use—by the consumers, 174
 real rate of, dependent on increases in production and supply of goods, 774–778
 uniformity-of-, principle, 172–187
 applications of: consumers' power to determine the relative size of the various industries, 174, 275; impetus to continuous economic progress, 176–180 (which contributes to capital accumulation by permanently raising productivity of capital goods and reducing maintenance proportion, 635); effect of business tax exemptions and their elimination, 183; effect of repeal of price controls, 180–183; keeping the various branches of industry in proper balance, 173–174, 275; makes businessmen act as agents of the consumers, 174–175, 275–276
 foundations of, 172–173, 183–185
 permanent exceptions to, 185–187

 distinctive nature of value and riches, 4, 487, 495–496, 539, 540, 715, 819 (*See also* Invariable money; Invariable-money/net-consumption analysis, applications/implications of)
- exposition of "Say's Law" superior to that of Say, 599(3)
- insights on capital accumulation, 3, 634, 819–820
- law of comparative advantage, 350
 limitless desire to consume, and economic problem as creation of purchasing power through increased production, 559–560
- preparing ground for net-consumption theory, 787, 797–798
- principle of invariable standard of value (invariable money), 4, 495–496, 537
- technological progress as reducing prices, not raising the average rate of profit, and, implicitly as being a source of capital accumulation, 3–4, 495, 819
- criticism of Say by, 414
- errors of (his belief in/that)
 concerning effects of changes in demand for labor, propounded in contemporary economics texts in form of balanced-budget-multiplier doctrine, 671(109)
- concerning effects of population increases, 358–360
- confusions concerning "iron law of wages," 494–495, 799–801
- contradiction of his doctrine of the distinction between value and riches in errors concerning effects of changes in the demand for labor, 639–641, 648–650
- cost of living determines wage rates independently of supply and demand for labor, 494–495
- denial of ability to tax wage earners, 497
- equivocations on meaning of wages, 798
- falling rate of profit unless offset by fall in cost of wage earners' necessities, 495, 799–801
- food becomes dearer with progress, 799
- misleading use of terms monopoly and competition in reference to the

- two patterns of price formation, 390; 438(22–23)
- natural price of labor as subsistence, 492
- rise, a, in demand for labor is always of benefit to wage earners, and thus that war and government spending can be of benefit to them, 648–650, 671(109)
- rise, a, in demand for machinery at the expense of the demand for labor is against the interests of wage earners, 639–641
- rise, a, in wage rates reduces profits rather than raises prices, 800
- use of fixed quantity of labor to produce an ounce of gold as basis of invariable standard of value, 537
- view that land rent would constitute an ever increasing share of national income, 310–316
- See also, below, “iron law of wages”; profit theory of
- quotation, in, from J. A. Hobson, 865
- quotation, in, from John Stuart Mill on demand for commodities is not demand for labor, 684
- “iron law of wages” xlvii–xlviii
- confusions and errors concerning, 494–495, 799–801
- reservations concerning, 492–493
- rent doctrine of, partly based on, 312, 473
- labor theory of value, limitations set by, on, xlvii–xlviii, 486, 500(100), 604
- differences in wage rates as a determinant of relative value, 489–490
- exclusion of scarce goods, 487, and, logically, of labor, 488, 500(102)
- implicit recognition of changes in the rate of profit as a determinant of relative value, 489, 795
- recognition of the time factor as a determinant of relative value, 488–489
- land-rent doctrine of, used by contemporary economics in treatment of recovery of fixed costs, 430
- leading classical economist, 1
- principle of resort to lands of progressively inferior fertility, 68, 311–312
- profit theory of, merit, deficiencies, and errors in 797–801
- profits and wages inverse relationship between, xlviii, 803
- actual meaning of, 495–496
- application of proposition in this book in critique of productivity theory of profit and interest in its traditional form, 798
- connection with John Stuart Mill’s proposition “demand for commodities is not demand for labor, 479, 485, 798
- contribution to critique of conceptual framework of Marxian exploitation theory, 479, 485
- implies all income is profit, not wages, in Adam Smith’s early and rude state of society, 479
- net-consumption theory implicit in proposition if taken in conditions of an invariable money, 797–798; 807(131–133)
- quotations from concerning/showing/stating
- actual meaning he attached to “a fall in wages” and inverse relationship between profits and wages, 496
- capital can be increased without its value increasing, even decreasing, 819
- capital increased by rise in productivity of labor as well as by saving, 819
- capital increased in same manner as wealth, 634, 819
- changes in the rate of profit as a determinant of relative value, 489
- competition of sellers, based on cost of production, as direct determinant of price of manufactured or processed goods below point corresponding to direct utility, 414
- exclusion of scarce goods from labor theory of value, 487
- fall in rate of profit checked by fall in prices of wage earners’ necessities, 496
- food becomes dearer with progress, 799
- implicit exclusion of labor from labor theory of value, 488
- limitless desire to consume, and economic problem as creation of purchasing power through increased production, 559–560
- market wages can be above subsistence indefinitely, 492
- natural price of labor as subsistence, 492
- profits fall as wages rise, interpretable as preparing ground for net-consumption theory, 797
- rate of profit falls because of rising cost of living of wage earners, 496
- rise in demand for labor always of benefit to wage earners, and thus war and government spending can be of benefit to them, 648
- rise in demand for machinery at the expense of the demand for labor is against the interests of wage earners, 639
- rise in population raises cost of living and wages, 494
- rise in wage *rates* [italics supplied] reduces profits rather than raises prices, because of foreign trade, 800
- rise in wages reduces profits, 495
- subsistence has variable meanings, 492
- technological progress as reducing prices, not raising the average rate of profit, and, implicitly as being a source of capital accumulation, 495, 819
- time factor as a determinant of relative value, 488–489
- use of invariable standard of value in his economic analysis, 537
- wages based both on demand and supply and on cost of living, 494
- wage earners have ultimate power over wages, 495
- Ricardo effect, critique of, 798–799
- Rights
- See Individual rights, including property rights
- Rising prices, inflation of the money supply vs. alternative theories of, 895–922
- demand/supply test for rising prices, elimination of falling supply, 897–907
- actual influence of supply has been to reduce prices, 898
- falling supply as the cause of inflation implies rapid disappearance of material civilization, 898–899
- falling supply as the cause of inflation implies that rising supply is a cause of deflation and depression, 907
- falling supply cannot explain the range of price increases that exists under inflation, 899, 901
- falling supply is incompatible with the debtor/creditor effects associated with inflation, 900, 901–907
- falling supply is the by-product of rapid increases in aggregate demand, 899
- where falling supply has contributed to rising prices, its role has been relatively minor, 898
- critique/refutation of the cost-push doctrines
- cost-push doctrine in general, 907–909
- crisis-push variant, 913–915
- profit-push variant, 911–913
- wage-price spiral variant, 915
- wage-push variant, 909–911

"Say's Law of Profits," 774–775

Scarcity, 54–61

 - capital and capital goods, of, 55–58, 556–557, 839
 - horizontal dimension of, varies with scarcity of corresponding consumers' goods, 56
 - Keynes' denial of, 858, 891–892
 - vertical dimension of, refers to the varying degrees of capital intensiveness that can exist in production, 56–58
 - capital funds, of, in an inflationary depression, 938
 - capitalism, as exists under, and as used in economics, refers primarily to limitless-

- ness of man's need and desire for wealth, not to a lack of urgently needed supplies, 54–55, 358–360, 542–602 *passim*
- basic facts underlying, as a permanent phenomenon, 42–51, 54
 - means a vast and growing supply of wealth that lags behind the desire for wealth, 54
 - present irrespective of abundance of supplies, 54
 - serves to prevent existence of, in urgent biological sense, 54–55
 - under precapitalist societies, means deficiency of wealth relative to urgent needs, 54
- concept of, differs from that of shortage, which only price controls can cause, 221
- caused by shortages, 221–222
- factors causing or reducing, as far as depends on production and supply
- capital accumulation and rise in productivity of labor reduce, 622–636
 - ecology movement (environmentalism) causes, 77–78, 80, 98–99, 316–317
 - economic competition reduces, 343–351, 357–360, 362–366
 - freedom of economic inequality reduces, 326–330
 - government intervention causes: *See* Capital accumulation, undermining of, by government intervention; Government intervention; Monopoly, political concept of, artificially restricts supply
 - price controls and socialism cause, 188–189, 211–212, 213–214, 222–228, 239–264 *passim*, 267–282
 - price system, free-market, and: lessening of, by speculation, 191; price controls no solution for, 190; profit motive operates continuously to diminish degree of, 172–174, 176–180; prospect of, leads to accumulation of stocks, 191, 193 (newsmedia confuse this fact with abundance, 193)
 - private ownership of means of production steadily reduces, 296–300, 306–310, 313–316
- influence of, on prices, 51–52, 152–155, 172–214 *passim*
- conceded by Ricardo and Adam Smith, but not sufficiently, 487–488, 493–494
 - confusions, exaggerations concerning: 167–169; by marginal-revenue doctrine, 408–423; by pure-and-perfect competition doctrine, 425–437
- labor, of
- artificial, caused by labor unions, with consequence of artificial surplus of labor elsewhere, or unemployment, 657–658
 - compounded by increased desire for leisure as productivity of labor rises, 60
 - compounded by scarcity of personal services, 60
 - creates the economic problem, which is the need continuously to overcome, through capital accumulation and raising the productivity of labor in framework of division of labor and capitalism, 9–10, 60–61, 123–128, 135–151, 618–636
 - determines money wage rates, rendering “worker need” and “employer greed” irrelevant, 613–618
 - extent of, 42–45, 59–60, 616
 - implies unemployment is a man-made phenomenon existing despite, 60, 580–584, 657–658, 659–660
 - implies wage rates go no lower than point of full employment, 616–618
 - ineradicable, 59–60, 580–581, 616
 - limits exploitation of natural resources, 75, 616
 - manifest in excess of income desired for spending in comparison with income capable of being earned, 59–60
 - not reduced by increases in the number of workers, who bring with them needs and desires far in excess of their ability to produce, 60
 - not reduced by increases in the productivity of labor, which are accompanied by new avenues of consumption as part of the same process, 60
 - underlies subsidiary problem of allocating existing limited ability to produce, to satisfaction of more important wants ahead of less important wants, 61
 - underlies the scarcity of wealth, 59
- land and natural resources, of, 63–76, 668
- no fundamental, of natural resources, including energy, 63–76, 698@SUBENTRY = marginal utility and, 51, 202, 206–214
 - no, of needs and desires or of work to be done, 42–45, 54–55, 59–60, 542–602 *passim*
 - no, of opportunities, including for employment, if not blocked by government intervention, 42–45, 59–60, 338–339, 542–594 *passim*

 capital accumulation, as source of
 capital accumulation ends in absence of, 557, 628–629
 capital goods, a leading source of supply of, 557, 629–631, 838–839; implicit recognition by Ricardo, 3–4, 634, 819
 constant returns to capital goods in face of law of diminishing returns made possible by, 628; thus allows increases in supply of capital goods to result in proportional further increases in supply of capital goods, 622–630, 710–711, 809–814; and makes relationship between saving and capital accumulation that of force to acceleration, not one-to-one, 622–630, 710–711, 809–814, 836, 839–840
 productivity of capital goods, maintained by, 628–629, 632
 productivity of capital goods subsumes contribution of, as source of capital accumulation, 634
 proportion of output required to maintain supply of capital goods (maintenance proportion), rises in absence of, 629
 reciprocal relationship between, and capital accumulation in that implementation of, depends on supply of capital goods and degree of saving and capital intensiveness, 132, 631–632, 824; average period of production sets limits to, as a source of, 824
 role of, in capital accumulation not seen by contemporary economics, 630–631

- errors concerning relationship between, and capital accumulation
 belief, implicit and contradictory, that, causes deflation by virtue of increasing supply of consumers' goods and thereby causing falling prices, 557–558
 belief, prevailing, that connection of, with capital accumulation is one of providing uses for additional capital goods provided by saving—that saving is sole source of capital accumulation, independently of, 556–558, 630, 838–840; belief, closely related, that, raises the rate of profit by raising “the demand for capital,” 558, 630
 claim that, deserves credit for most of the increase in production, as *opposed* to capital accumulation, 630–631, 777
 profits and
 basic neutrality of, with respect to average rate of profit in economic system, 558; raises profits of innovators, but lowers profits of others, 558; *see also* Uniformity-of-profit principle
 only connection between, and average rate of profit is via increases in the supply of commodity money, to which it contributes, 558; and in that case, it is source of continuation of nominal net investment and thus continuing increase in supply of nominal capital, 818–819; profitability for the additional nominal capital provided not by, but by the process of net investment itself, 818–819
 neutrality of, with respect to average rate of profit, recognized by Ricardo, 495, 819
 socialism, in contrast to capitalism, lacks incentives to develop and implement, especially if only of benefit to the plain citizens, 275–277
 socialized medicine and collectivization of costs of medical care make, in medicine a threat to government's budget, 149
 valuable as a source of supply of capital goods, not of uses for capital goods, 556–558
 war and, 277, 294(16), 551

Wage earners, saving of
See Net consumption, relationship to the saving of wage earners

Wages-fund doctrine, 3, 11, 474, 487–488
 Wage-push doctrine
See Rising prices, inflation of the money supply vs. alternative theories of

Wage(s) (rate[s])
 defined, 478
 determined by demand and supply of labor, through competition of employers for scarce labor 613–618
 irrelevance of worker need and employer greed, 613–618
 scarcity of labor, extent of, 42–45, 59–61, 201

demand for labor as determinant of
 created by businessmen and capitalists, 140–141, 298, 478–480, 613–618, 682–691
 depends on saving and productive expenditure and economic degree of capitalism, 140–141, 478–480, 621, 632–634, 682–691, 694–696; and on private ownership of the means of production and respect for property rights as foundations thereof, 19–20, 58, 139, 280, 300–303, 306–310, 622–641, 642, 644, 651–654, 743–744

futility of raising by means of: increase in the quantity of money and volume of spending, 646–647; reduction in the demand for capital goods, 647; taxation, 648–650
 not constituted by demand for consumers' goods, 140–141, 478–480, 682–691
 reduced by progressive personal income and inheritance, corporate income, and capital gains taxes, 636
 rise in, raises real wages only when based on fall in net consumption (including government spending that takes place at the expense of productive expenditure), 650–653

fall in, necessary to eliminate unemployment, 580–588, 883–884
 effect of fall in, as part of process of achieving full employment, on real wages and profitability, 583–588
 failure of, to fall prolongs and deepens the depression, 589–590; blocks the springs to profitability, 784
 fall in, no greater than to full-employment point, in free market, 616–617; fall below full-employment point causes labor shortage, which is against the interests of employers, 616–617

fallacy of converting profits into a source of additional, 654–655
 fallacy of primacy of, 477–478
 formula for, 569, 581, 584, 618–621, 660
 fringe benefits at expense of take-home, 645, 662–663
 real
 businessmen and capitalists responsible for continuously raising, by virtue of achieving continuous capital accumulation (through ensuring sufficient relative production of capital goods on basis of saving, and establishing and maintaining high productivity of capital goods), which continuously raises productivity of labor, 176–180, 299, 302, 622–636, 737–739, 809–824, 826
 defined, 618
 determined in first instance by productivity of labor, which determines relationship between average money wage rate(s) and general consumer price level, 618–622; also determined, within strict limits, by "distribution factor" (i.e., demand for labor relative to demand for consumers' goods), 621
 economic degree of capitalism determines both productivity of labor (insofar as capital accumulation depends on relative demand for capital goods) and "distribution factor," 633–634
 economic degree of capitalism in turn determined by saving and produc-

- tive expenditure of businessmen and capitalists, 478–480, 622–629
 effect of achieving full employment on, 583–588
 effect of employment of women and minorities on, 663–664; different under minimum-wage laws and quotas than under freedom of competition, 664
 formula for, equals the product of the productivity of labor times the “distribution factor,” 621
 free immigration into capitalist country increases in long run, 362–363
 invariable-money/net-consumption analysis, implications of, for process of raising, 826
 limited scope for raising, through a rise in the demand for labor, 650–653
 population increases in capitalist country, increase in long run, 360–361
 productivity theory of wages as explanation of, 613–668
 raised, despite fall in money wage rates, by rise in the demand for capital goods coming at the expense of the demand for labor, 639–640
 reduced by all government intervention that needlessly raises costs, 98, 175–176; *see also* Government intervention
 reduced by all government intervention that undermines capital accumulation, via reducing saving and thus relative demand for and production of capital goods, and/or productivity of capital goods, 98–99, 110, 260–261, 300–303, 306–310, 636–639, 653–655, 826–829, 829–831, 927–928, 930–937
 reduced by efforts to raise money wage rates through restricting the supply of labor, 646–647, 657–658, 659–660
 reduced by labor unions, minimum-wage laws, and labor and social legislation in general, 653–663
 resumption of rise in, requires radical reduction in government intervention, to restore capital accumulation and economic progress, 98–99, 110, 260–261, 300–303, 306–310, 636–639, 653–655, 826–829, 829–831, 927–928, 930–937
 rise in, caused by creation, coordination, and improvements in efficiency of division of labor achieved by businessmen and capitalists, 145–147, 172–218 (especially 176–180), 298–300, 306–316, 326–330, 343–358, 464, 622–663
 rise in, depends on private ownership of the means of production and respect for property rights as essential conditions underlying
- continuous capital accumulation and rise in productivity of labor, 176–179, 277–278, 298–316, 622–641, 642, 644, 651–654, 743–744, 826–829
 scope for raising, through a rise in the demand for labor not present in case of a matching increase in supply of labor drawn from ranks of nonwage earners, 652–653
 take-home, higher with full employment than with mass unemployment, 618
 relative productivity as a determinant of, of individuals and competing groups, 655–657
 relative to demand for labor
 set too high, as by unions and minimum wage laws, cause unemployment, 580–583, 646–647, 657–658, 659–660
 set too low, as by wage control, cause labor shortage, 613–618
 subsistence
 prevail under socialism, 275–278
 self-interest of capitalist employers in mutual competition prevents, 613–618; rising productivity of labor under capitalism raises real wages ever further above subsistence
 See also “Iron law of wages”
 supply of labor, as determinant of
 artificial decreases in, raise money, while reducing real, 646–647, 657–658, 659–661
 increases in, in free economy operate to reduce money, while not reducing or even raising real, 358–366, 581–588, 620–621, 663–664
 uniformity of, for workers of same degree of ability, tendency toward, 194–199; exception in free immigration into capitalist countries from unfree countries, 366
See also Businessmen and capitalists; Capital accumulation; Economic progress; Harmony of interests; Individual rights, including property rights; Labor, demand for; Labor, productivity of; Laissez faire (capitalism); Private ownership of the means of production; Productionism; Productive expenditure; Productivity theory of wages; Saving(s)

 Wealth
- capital, a subcategory of, 132, 148
 consumptionist confusions concerning
 absence of, viewed as asset 550
 creation of need and desire for, rather than production of, considered basic problem of economic life, 543–545, 549–556
 depressions believed to be caused by “overproduction” of, 544–546
 defined, 39
 dependence of production of, on division of labor, 123–128
 distinguished from:
 money and monetary value in general, 39; *see also* Invariable money
 property possessing market value, such as: licenses and legal rights, including those conferred by patents and copyrights; stocks, bonds, and bank deposits; slaves in a society permitting slavery, 40
 earning of, objectively deserving of prestige, 47
 goods, and, 39–41
 economics a science of, 15, 19, 41–42
 increase in
 See Businessmen and capitalists; Capital accumulation; Capitalism; Economic progress; Freedom; Individual rights, including property rights; Laissez faire (capitalism); Private ownership of the means of production; Saving(s)
 importance of, 15, 39–62
 includes natural resources in the ground, 59
 includes precious metals, 39
 labor, and, 58–61
 limitless need and desire for
 essential cause, an, of continuous economic progress, 45–46
 how reconciled with existence of economic stagnation, 45
 human reason and the scope and perfectibility of need satisfactions: abstract argument, 43; extent of wealth needed: to enhance the power of man’s limbs and senses, 43; to serve man’s “higher” needs, 43–44; “lower” needs, 44; need for nutrition and health, 43; need for novelty and variety, including style changes, 44–45; psychological and aesthetic needs, 44
 marginal utility, law of diminishing, reconciliation with, 49–51
 manifested in continuing valuation of goods of earlier eras, 48
 source of happiness, not discontent, 45–46
 objectivity of value of, implies objectivity of value of division-of-labor, capitalist society, 48
 production of, not measured by GDP or GNP, 39–40
 requirements of things becoming, 40–41
 result of human labor, 58

- scarcity of
 not the result of scarcity of natural resources, 59
 rests on more fundamental scarcity of human labor, 59
 service industries auxiliary to production of, 41–42
 valuation of prestige above, the mark of a fool, 47
See also Capitalism; Capital goods; Good; Production; Productionism
- Wells, H. G., 110
- Western (capitalist) civilization
 implicit racism of view that it is civilization of the white man, 48
 objective basis for claiming superiority of, 48
 universalizability of, 48
 why Anglo-Saxon variant of, is objectively highest form of civilization thus far, 48
